To summarize, the morphologic method described should be used to diagnose and to name the cardiac chambers. In single right ventricle, accurately speaking, the left ventricle is absent (not just small). A valid distinction exists between double inlet right ventricle and common inlet right ventricle with a biventricular heart (large right ventricle and small left ventricle) on the one hand, and double inlet right ventricle and common inlet right ventricle with single right ventricle (large right ventricle and absent left ventricle) on the other. Shinebourne et al.[1] presented double inlet right ventricle, common inlet right ventricle, and mitral atresia in biventricular hearts with a large right ventricle and a small left ventricle. The classic definition of single ventricle is not satisfactory for 3 main reasons: (1) it is wrong in principle; (2) it violates the morphologic method; and (3) it has numerous well-documented exceptions. Consequently, this unsatisfactory old definition should not be used as a model (paradigm) for deciding what is a ventricle versus what is merely a "rudimentary chamber." Naming ventricular chambers in terms of the degree of straddling of the A-V valves is wrong in theory and also leaves much to be desired in practice: As exemplified previously, this approach is anatomically inaccurate, diagnostically impractical, and surgically unhelpful. No one can take refuge in a definition when that definition is unacceptable. Nor should anyone wish to. There is no good reason to insist on applying the classic concept of single ventricle when modern morphologic anatomic analysis and the principles of logic both indicate that this old concept is untenable. Instead, we should all adhere to the morphologic method of diagnosing and naming the cardiac chambers in complex congenital heart disease[2–5,11] because this approach is acceptable both in theory and in practice. Many scientific controversies are not really disagreements at all, but rather are the results of misunderstanding. This is the root problem here. Precisely what is wrong with the classic definition of single ventricle has not been clearly understood until recently. Hence, it has not been widely appreciated that attemptes to apply this old approach in an effort to redefine what a ventricle is (and is not) are similarly unacceptable. Together, all serious students of congenital heart disease must choose an approach that is, and

will continue to be, satisfactory for the field as a whole. The approach must be sound. We must not choose, or defend, an approach that we all should now know is wrong in theory, and unsatisfactory in practice.

REPLY

We have carefully analyzed the letter of Van Praagh and his colleagues, as, indeed, we analyzed with similar care their earlier letter[1] concerning the work of Soto et al. on the anomaly under discussion. In descriptive terms, the malformations described had their atrial chambers connected only to a morphologically right ventricular chamber in presence of a second left ventricular chamber which lacked an atrioventricular connection. It seems that Van Praagh et al. object to this anomaly being considered as "single right ventricle." We sympathize with them in this respect, which is why we specifically chose *not* to call the hearts "single right ventricle." Reading their letters we infer that the major concern of Van Praagh et al. is to preserve the purity of their own definitions of single ventricle. It is precisely because we respect this prerogative that we chose the term "univentricular" rather than "single ventricle" when looking for a word that would group together several congenital malformations which, among themselves, differed in other aspects of morphology. We believe that the concept that justifies this grouping is entirely logical, is internally consistent, and is based completely on observed morphology. It would be possible to rebut each of the criticisms of Van Praagh's group in turn, but it is perhaps better to try to summarize the basis of our own method for categorization of hearts in general,[4] but particularly the hearts we choose to group as univentricular.[5–8]

The system we advocate is based on analysis of the junctions of the heart in terms of type and mode of connection, analysis of the chambers and great arteries in terms of both observed morphology and their size and analysis of the interrelations of chambers and arteries. All features are described when necessary, but with mutually exclusive terms. Considering this in the light of our use of "univentricular," congenital malformations as a whole can be divided into 2 groups on the basis of their atrioventricular (A-V) connections. In by far the largest group, there is a one to one connection between the atria and the ventricles. In the second group, only one ventricular chamber is connected to the atria. A second ventricular chamber, if present in this group, lacks an A-V connection. The chamber that lacks an A-V connection can vary markedly in size (which we describe) without this affecting its basic morphology. To argue that this difference in connection or nonconnection of a ventricular chamber to the atria does not alter its own intrinsic morphology—which we understand is what Van Praagh et al. suggest—is reducing the situation to the absurd. It suggests that Occam's razor, when wielded without care, has the effect of a guillotine.

In the group with one to one A-V connections, each ventricular chamber is connected via a parietal A-V junction to an atrial chamber. This fact can be recognized simply by examining the structure of each ventricular chamber. Equally, in the other group with only one ventricular chamber connected to the atria, this structure can again be determined solely by examining the ventricular chambers. The basic feature that unifies the hearts we have chosen to term "univentricular" is therefore that they posses only 1 ventricular chamber that is connected to the atrial chambers. Whether or not this is based on old flawed definitions is neither here nor there. The grouping together of these hearts recognizes a feature of major diagnostic, clinical, and surgical significance that warrants attention from all those interested in congenital heart disease. The hearts that are justifiably unified by this morphologic feature can, of course, differ in respect to the detailed morphology of their ventricular mass. This also demands description in unambiguous fashion. From our observations and those of many others, we conclude that hearts with the A-V junction connected to only one ventricular chamber can have three basic patterns of morphology. The most common is when the chamber connected to the atria has left ventricular morphology and the chamber lacking an A-V connection has right ventricular morphology. Although Van Praagh et al. claim that this second chamber is solely an infundibulum, our observations[4–8] militate against this possibility. Indeed, our findings suggest unequivocally that it possesses a trabecular component of right ventricular type. This trabecular component can exist in isolation when both outlets are connected to the left ventricular chamber.[7] Our further observations show that a second variety of hearts exists with the atria connected to only 1 ventricular chamber. This second variety is entirely analogous to the first variety. The first variety is described by Van Praagh and colleagues as "single left ventricle." The second variety is characterized by the chamber connected to the atria having right ventricular characteristics and that not connected to the atria having left ventricular characteristics.[3,8,9] Our observations show that this unequivocally left ventricular chamber, recognizable from its own morphology as lacking an A-V connection, can also exist in isolation as a trabecular component when both outlets are connected to the right ventricular chamber, or can have its own outlet portion.[8,9] Our observations go further still in that they indicate that a third comparable variety of hearts exist in which the A-V connection is committed to a sole chamber in the ventricular mass.[8] This sole chamber is characterized by neither right nor left ventricular trabecular patterns but has an indeterminant pattern. The final vital point we have found is that any of these 3 ventricular morphologies—left

ventricular main chamber with right ventricular rudimentary chamber, right ventricular main chamber with left ventricular rudimentary chamber, or sole chamber of indeterminate morphology—can exist when the A-V connection is double inlet or when either the right or left A-V connection is absent.[8] When a rudimentary chamber is present, the A-V connection cannot be determined simply by examining the rudimentary chamber, since its morphology of either right or left ventricular type is virtually identical be there double inlet or absent connection.[6,8]

Van Praagh and his colleagues are perhaps most concerned with our treatment of hearts with straddling and overriding valves. It is generally accepted that such hearts make up a series of anomalies between hearts with one-to-one atrioventricular connections and those with the atria connected to only 1 ventricular chamber. There are 2 ways of dealing with such a series. The first is to consider such hearts as a discrete type of connection. The second is to consider an overriding valve as a mode of connection, and to divide the series of which it is a part at its mid-point, categorizing only the 2 ends of the series in terms of atrioventricular connections. It is the latter approach which we adopt. But then the decision regarding categorization is not arbitrary, it is determined by the observed structure of the overriding valve and its precise connections to the underlying ventricular chambers.

The vital point, therefore, which Van Praagh and his colleagues apparently misunderstand, is that although we are concerned with the effect that inlets and outlets have on ventricular morphology, and are equally concerned about chamber size, we do *not* define ventricular morphology solely in terms of a valve of entry. We try to describe all features of ventricular morphology, both their architecture and their size. A ventricular chamber of any type is given specificity by its trabecular component, be it that of left ventricular, right ventricular, or indeterminate type. Indeed, the term "ventricle" itself is as nonspecific as is "outlet chamber" or "trabecular pouch" when unequalified as to the nature of its trabecular component. Simply from observed morphology it is evident that right and left ventricular chambers can exist together, both having inlet and outlet components as in the normal heart. Right and left ventricular chambers can also exist together when 1 has an inlet alone and the other has an inlet and both outlets as in double outlet ventricles. These structures are found only in hearts with one to one A-V connections. But equally left and right ventricular chambers can exist together when 1 ventricular chamber lacks an inlet component. The atrial chambers are then either both connected to the other ventricular chamber, or else one atrium has no A-V connection. In this setting, the very finding of a ventricular chamber *without* an A-V connection, which we choose to call a rudimentary chamber, announces almost without exception that the A-V junction is connected to only 1 ventricular chamber. But this finding also makes it necessary to give specificity both to the chamber connected to the atria (which we call a ventricle) and to the chamber lacking an A-V connection (the rudimentary ventricular chamber). This must be done not only by describing their being of right or left ventricular type but also by describing their size. It also makes it necessary to determine the precise A-V connection present. Indeed, the recognition that a heart belongs to the group we term "univentricular" sets in motion a train of events that leads inexorably to the correct clinical diagnosis.

What is questionable is whether we are justified in using the term "univentricular" for grouping together these hearts. We have in fact commented on the literary inadequacy of using the term "univentricular" for describing hearts possessing 2 ventricular chambers.[7] We stated clearly at that time that the only justification for using "univentricular" in this fashion was the continuing use of "single ventricle" to describe hearts possessing 2 ventricular chambers. Van Praagh et al. are therefore incorrect when they imply that we are unacquainted with the deficiencies of the classic definition of "single ventricle." But it is evident even from this recent letter that the classic convention is still very much alive, and that he and his colleagues still describe as "single ventricle" hearts that possess 2 chambers within their ventricular mass. Investigators must use the terminology most suited to their needs. In the case of hearts in which the A-V junction is connected to only 1 ventricular chamber, and in the differentiation of these hearts from each other and from other hearts with imperforate A-V valves, we find our own described nosology[8–10] most adequate. We see no reason to change this nosology, which is of immense value in clinical situations, simply because it contravenes the purity of definition of an anomaly that other authorities would term "single right ventricle." Our own system caters for all examples known to us of what might be termed "single ventricle" and also groups with them many analogous hearts. We find no new evidence within the comments of Van Praagh and his colleagues that warrants change in their approach.

The most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

Please see next page for a summary of prescribing information.

Nitro-Dur
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 10cm², 15cm² and 20cm², containing 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCJ2

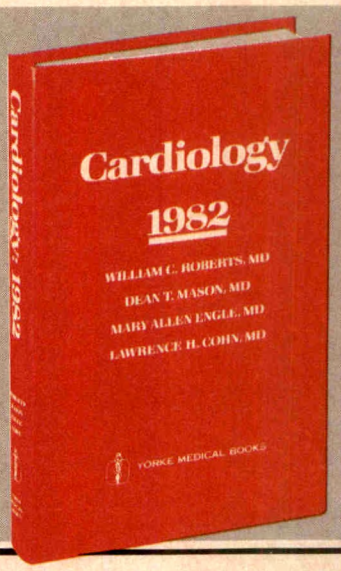
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

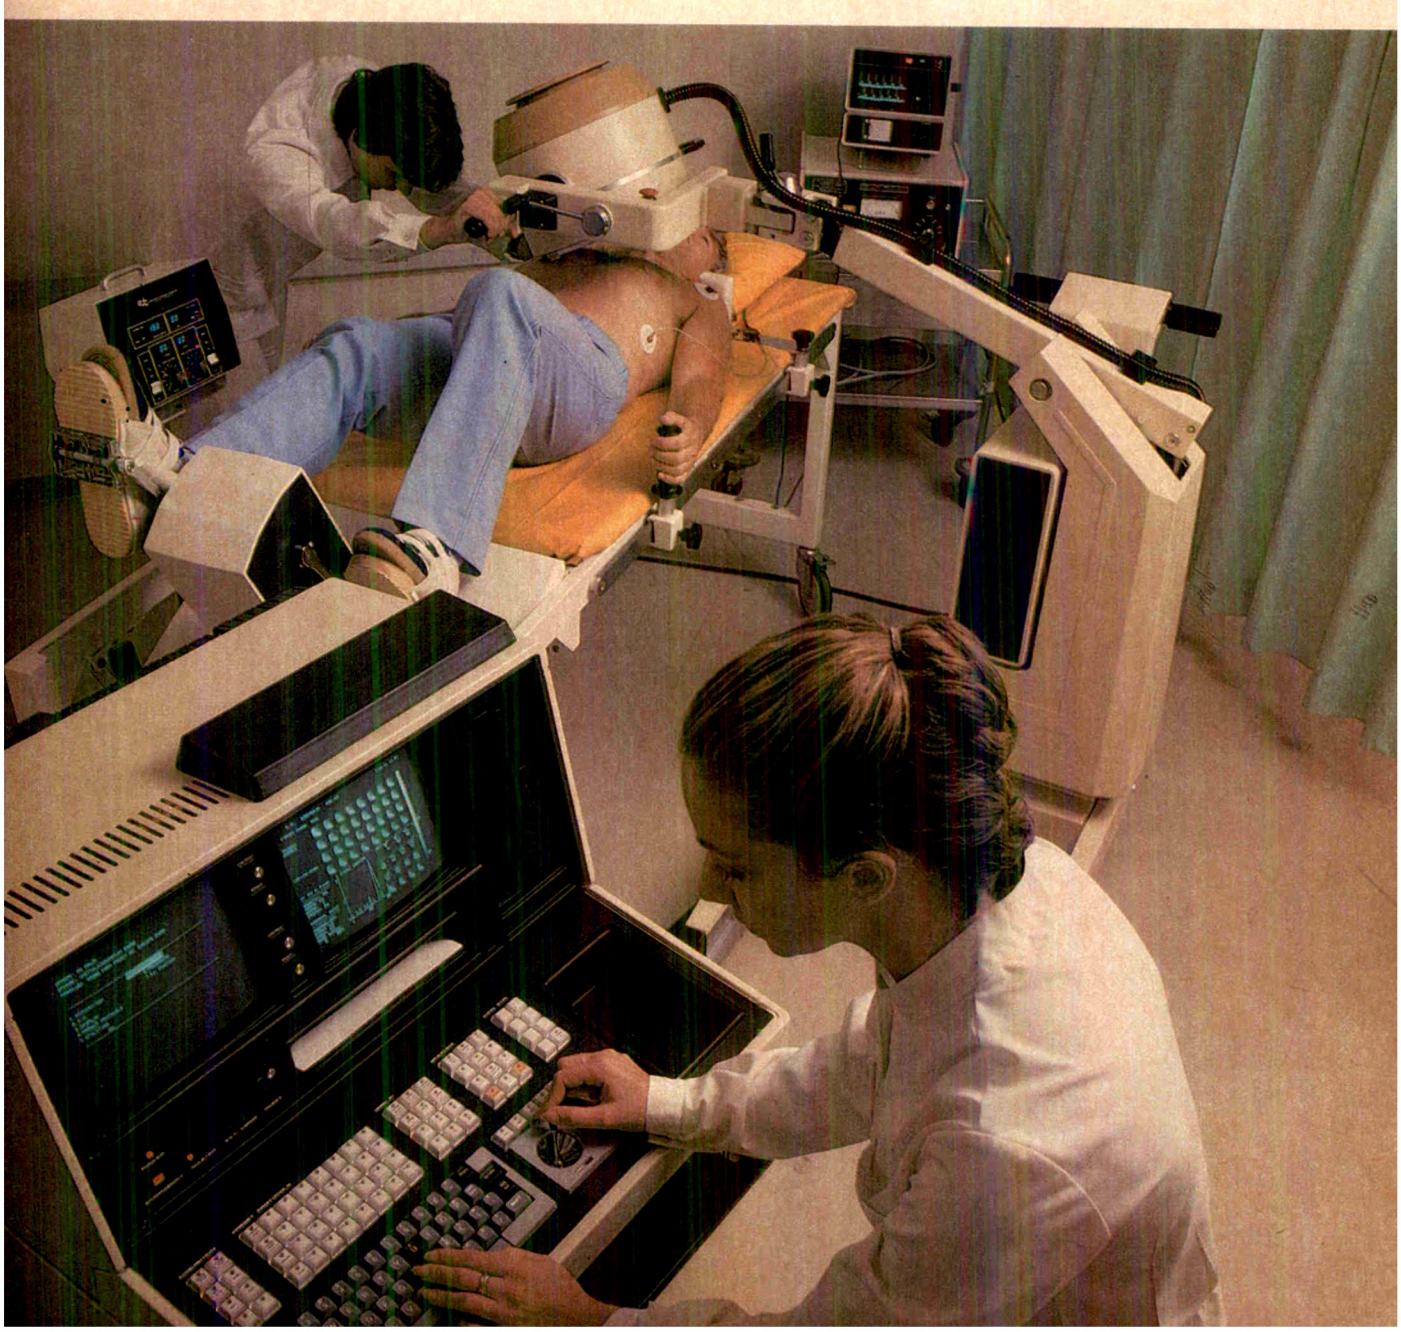
radionuclide cardiography comes of age

Apex 215M

The Cardiologist's Own Nuclear Camera

Visit our Booth at the Meeting of the American Heart Association in Dallas. November 15-18, 1982



Nuclear Cardiology: it grows more authoritative every day. Apex 215M is fast becoming the first choice in cardiac nuclear imaging. And with good reason.

Universal Cardiological Capability

Apex 215M is a compact digital nuclear camera — fully mobile and exceptionally maneuverable.

Apex 215M's image quality is far superior to that of any other camera. Clinical count rates in first-pass studies exceed 200K CPS. Resolutions of 1.8 mm bars are particularly valuable in Tc and Tl scintigraphic studies of myocardial infarction and ischemia. And superfast data handling enables rest/exercise equilibrium studies at 64 frames per cycle.

Dedicated Cardiological Software

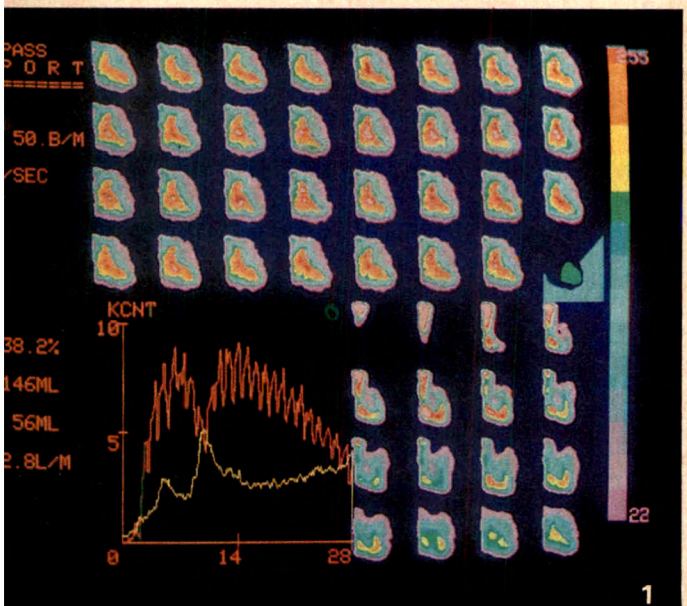
Today's knowledgeable physician appreciates Apex 215M's broad spectrum of dedicated software:

- Global and Regional Ejection Fraction
- End Diastole/Systole Volumes
- Paradox Imaging
- Fourier, Phase and Amplitude Imaging

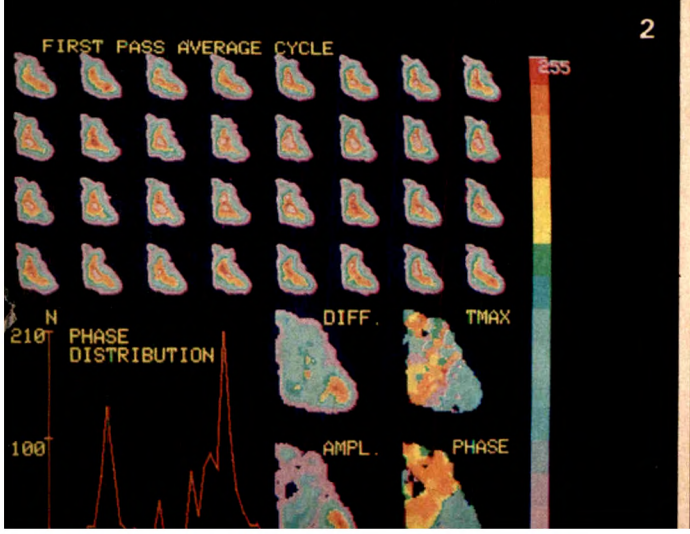
and many more. And an entire new series of Apex cardiological programs is currently being tested.

elscint inc.

930 Commonwealth Avenue,
Boston, MA 02215, U.S.A.
Call Toll Free: 800-343-9504.

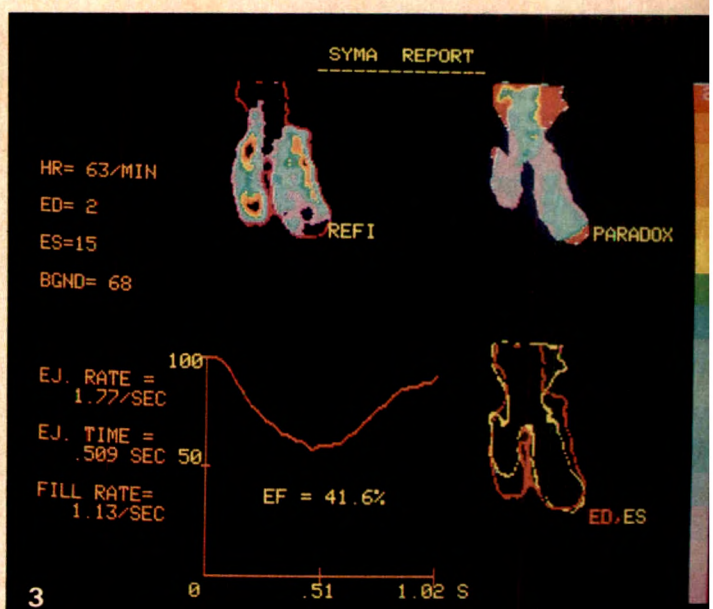


1

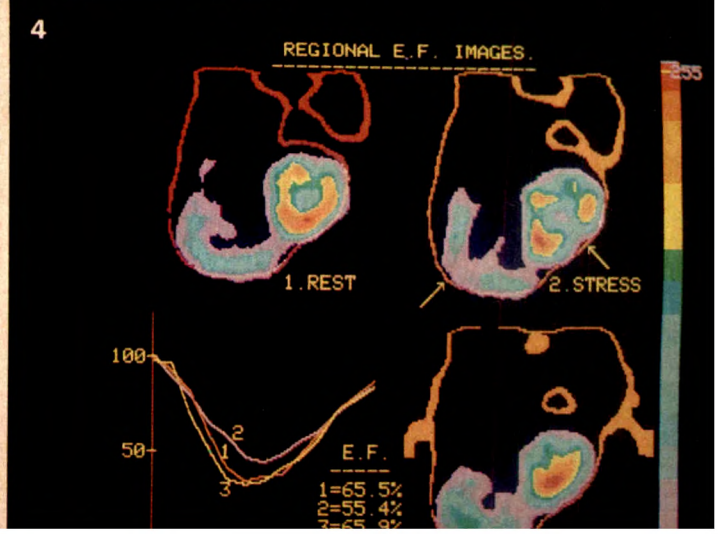


2

Photos 1 & 2: Apex 215M's high count rates enable superior definitive first-pass studies. Typical of its capabilities are global and regional ventricular function analysis and direct quantification through volume.



3



4

Photos 3 & 4: Apex 215M can clearly display various global and regional functions on a single image monitor. In these examples, ventricular functions in a resting heart appear above; the lower image compares the resting heart with two different intervention situations.

SLOW-K® potassium chloride slow-release tablets

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS

Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION

Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

CIBA

Xylocaine®
(lidocaine HCl) Solution
Intravenous Injection for Ventricular Arrhythmias

Before prescribing or administering, please consult complete product information, a summary of which follows:

INDICATIONS

Xylocaine brand of lidocaine HCl administered intravenously is specifically indicated in the acute management of (1) ventricular arrhythmias occurring during cardiac manipulation such as cardiac surgery, and (2) life-threatening arrhythmias which are ventricular in origin, such as occur during acute myocardial infarction.

CONTRAINDICATIONS

Xylocaine brand of lidocaine HCl is contraindicated in patients with a known history of hypersensitivity to local anesthetics of the amide type. Xylocaine brand of lidocaine HCl should not be used in patients with STOKES-ADAMS syndrome, Wolff-Parkinson-White syndrome, or with severe degrees of sinoatrial, atrioventricular, or intraventricular block.

WARNINGS

Constant monitoring with an electrocardiograph is essential to the proper administration of Xylocaine brand of lidocaine HCl intravenously. Signs of excessive depression of cardiac conductivity, such as prolongation of PR interval and QRS complex and the appearance or aggravation of arrhythmias, should be followed by prompt cessation of the intravenous infusion of this agent. It is mandatory to have emergency resuscitative equipment and drugs immediately available to manage possible adverse reactions involving cardiovascular, respiratory, or central nervous systems.

Occasional acceleration of ventricular rate may occur when Xylocaine brand of lidocaine HCl is administered to patients with atrial fibrillation. Evidence for proper usage in children is limited.

Usage in Pregnancy: It is not known whether Xylocaine brand of lidocaine HCl may have adverse effects upon fetal development. The benefits of the drug to the mother should be weighed against the possible risk to the fetus.

PRECAUTIONS

Caution should be employed in the repeated use of Xylocaine brand of lidocaine HCl in patients with severe liver or kidney disease because accumulation may occur and lead to toxic phenomena, since Xylocaine brand of lidocaine HCl is metabolized mainly in the liver and excreted by the kidneys. The drug should also be used with caution in patients with hypovolemia and shock, and in all forms of heart block (see CONTRAINDICATIONS and WARNINGS).

In patients with sinus bradycardia or incomplete heart block, the administration of Xylocaine brand of lidocaine HCl intravenously or the elimination of ventricular ectopic beats without prior acceleration in heart rate (e.g., by isoproterenol or by electric pacing) may promote more frequent and serious ventricular arrhythmias or complete heart block (see CONTRAINDICATIONS).

ADVERSE REACTIONS

Systemic reactions of the following types have been reported:

1) Central Nervous System:
Light-headedness; drowsiness; dizziness; apprehension; euphoria; tinnitus; blurred vision or double vision; vomiting; sensations of heat, cold or numbness; twitching; tremors; convulsions; unconsciousness; respiratory depression and arrest.

2) Cardiovascular System:
Hypotension; cardiovascular collapse; and bradycardia which may lead to cardiac arrest.

3) Allergic reactions may occur but are infrequent. There have been no reports of cross-sensitivity between Xylocaine brand of lidocaine HCl and procainamide or between Xylocaine brand of lidocaine HCl and quinidine.

MANAGEMENT OF ADVERSE REACTIONS

1) In the case of severe reaction, discontinue the use of Xylocaine brand of lidocaine HCl.

2) Institute emergency resuscitative procedures and administer the emergency drugs necessary to manage the severe reaction. For severe convulsions, small increments of diazepam or an ultrashort acting barbiturate (thiopental or thiamylal); or if those are not available, a short-acting barbiturate (pentobarbital or secobarbital); or if the patient is under anesthesia, a short-acting muscle relaxant (succinylcholine) may be given intravenously. Muscle relaxants and intravenous medications should only be used by those familiar with their use. Patency of the airway and adequacy of ventilation must be assured.

3) Should circulatory depression occur, vasopressors, such as ephedrine, or metaraminol may be used.

HOW SUPPLIED

For direct injection Xylocaine brand of lidocaine HCl without preservatives is supplied in 5 ml, 100 mg ampules and in 5 ml, 100 mg prefilled syringes.

For preparing intravenous infusion solutions, Xylocaine brand of lidocaine HCl without sodium chloride or preservatives is supplied in one and two gram additive syringes and in one and two gram single use vials. Each vial is packed with a pre-sterilized transfer unit manufactured by the West Company.

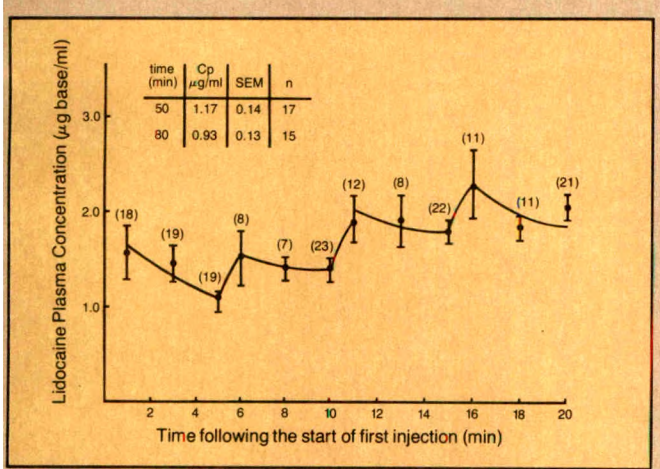
Advances in Cardiac Antiarrhythmic Techniques

INFARCT

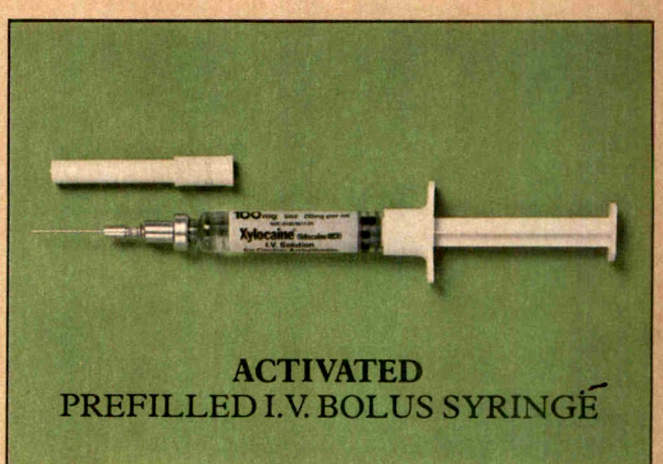
Multiple bolus injections of Xylocaine® (lidocaine HCl) Solution in the first 16 minutes of administration may control refractory ventricular extrasystoles.[1]



Plasma concentration-time data (mean ± standard error of the mean [SEM]) observed after administration of a total of 225 mg of lidocaine in divided bolus doses every 5 minutes over a 16-minute period. Cp = plasma concentration; n = number of plasma determinations at 50 and 80 minutes; figures in parentheses = number of plasma determinations at the times indicated.[1]

In patients with acute myocardial infarction, serious ventricular extrasystoles sometimes continue to occur even after an initial bolus dose of 75 mg lidocaine and concomitant 2 mg/min lidocaine infusion. Multiple bolus injections of 50 mg lidocaine — every 5 minutes if necessary to a total of 225 mg lidocaine — have been shown to be a safe way to provide effective, nontoxic blood levels of lidocaine in these patients.[1] In 23 patients given divided doses of 75, 50, 50, and 50 mg lidocaine by bolus injection at 5-minute intervals over a 16-minute period, no plasma concentration greater than 4.8 μg/ml was observed. Plasma concentrations stayed well within the accepted therapeutic range during virtually all of this period.[1]

When your protocol calls for multiple bolus injections of lidocaine, choose the Xylocaine® I.V. Bolus 100 mg Syringe.



ACTIVATED
PREFILLED I.V. BOLUS SYRINGE

The locked needle guard ensures sterility, and indicates the needle has not been exposed. The calibrated barrel has clear markings for 100 mg and 50 mg doses, simplifying administration. And the finger grips make it easy to administer slowly a controlled I.V. bolus injection. Remember that NO MORE THAN 200 TO 300 MG OF LIDOCAINE HCl SHOULD BE ADMINISTERED DURING A ONE-HOUR PERIOD.

PACING!

Announcing a unique, noninvasive emergency pacemaker

PACE AID™

The major remaining problems in the management of cardiac arrest are asystole and severe bradycardia....

Now PACE AID provides immediate therapy

- ☐ easy application with anterior/posterior adhesive electrodes
- ☐ portable/battery powered
- ☐ buys time to start endocardial pacing
- ☐ for ED, ICU, CCU and mobile cardiac care units
- ☐ no defibrillator should be without one

Cardiac arrest patient with asystole and ventricular escape beat.

Noninvasive PACE AID pacing at 80/min – blood pressure 110/80 mm Hg.*

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, andparoxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreas excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digox (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases whe the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: Th drug should be used with caution due to excretion of the quinidine in breast milk. ADVERS REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/ disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTES TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QR complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricul tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMA TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranul cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, an syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasi blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, nigh blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intens pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episod vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribin Information.

When more than a thiazide is needed...

ALDOMET® TABLETS 500 mg, 250 mg, and 125 mg (METHYLDOPA | MSI

an agent well matched to the prc fil

With increasing age...
incidence of certain concurrent disorders increases

ALDOMET may be used in a wide range of older hypertensives, including those with:

- **ventricular hypertrophy/cardiac failure***
- **peripheral vascular disease**
- **diabetes mellitus**
- **hyperuricemia/gouty arthritis**

judicious exercise may be desirable

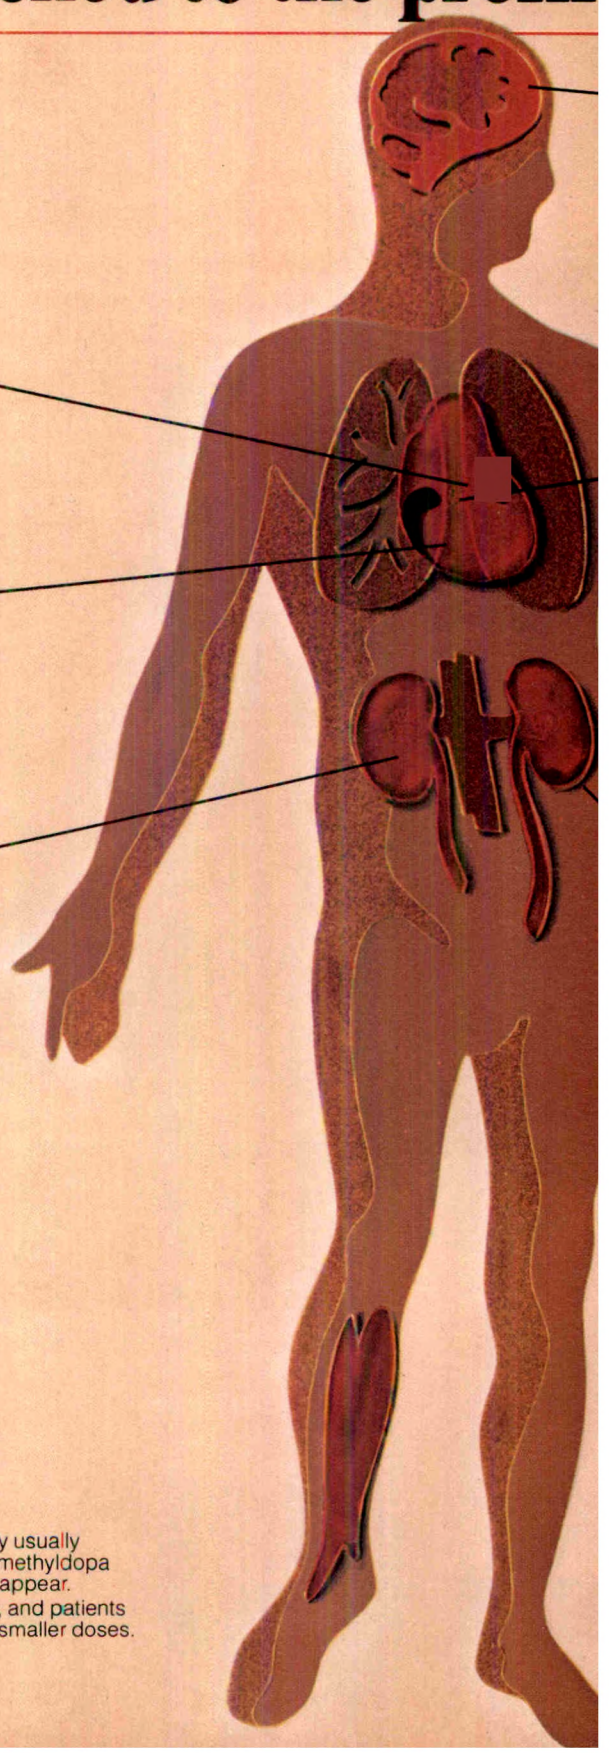
ALDOMET usually does not interfere with the cardiovascular response to exercise.

renal function often diminished

ALDOMET usually does not reduce glomerular filtration rate, renal blood flow, or filtration fraction.†

compliance often a problem

ALDOMET provides b.i.d. dosage convenience for many patients.



*Edema (and weight gain) may occur and may usually be relieved by use of a diuretic. Discontinue methyldopa if edema progresses or signs of heart failure appear.

†Methyldopa is largely excreted by the kidney, and patients with impaired renal function may respond to smaller doses.

Copyright ©1981 by Merck & Co., Inc. All rights reserved.

# of a wide range of older hypertensives

ability to autoregulate cerebral blood flow with postural changes often decreased

With ALDOMET® (Methyldopa, MSD), symptomatic postural hypotension is infrequent. Syncope in older patients may be avoided by lower doses.

cardiac output and heart rate usually normal

ALDOMET has no direct effect on cardiac function, and cardiac output usually is maintained.

total peripheral resistance usually high

ALDOMET lowers blood pressure, apparently by lowering total peripheral resistance.

ongoing therapy usually required

ALDOMET has demonstrated a high degree of efficacy in long-term therapy.

plasma renin activity usually low but may be normal or high

With ALDOMET, normal or elevated plasma renin activity may decrease.

ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, or if previous methyldopa therapy has been associated with liver disorders.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed.

Syncope in older patients may be related to an increased sensitivity and advanced arteriosclerotic vascular disease. This may be avoided by lower doses.

MSD
MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see following page.

ALDOMET® (MethyldopaIMSD)

Tablets, containing 125, 250, or 500 mg methyldopa; Oral Suspension, containing 250 mg methyldopa per 5 ml and alcohol 1%.

Contraindications: Active hepatic disease: such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions. With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood. At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients. Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient, dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements, psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, prolonged carotid sinus hypersensitivity, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, colitis, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Bone marrow depression, leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Dermatologic:* Rash as in eczema or lichenoid eruption; toxic epidermal necrolysis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, hyperprolactinemia, amenorrhea, impotence, decreased libido, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

FROM THE EDITOR

Reviewing Manuscripts: Occasionally a Test of Character

One of the least appreciated tasks performed by members of the medical academic community is their objective review of manuscripts submitted to them by the editors of medical journals. Although occasionally a reviewer may be able to evaluate a manuscript in only a few minutes, most reviews require much longer.

Reviewing a manuscript can sometimes be a test of character. A manuscript sent to a reviewer often concerns a subject about which the reviewer himself has contributed information previously, or a subject he is currently investigating or planning to investigate. Thus, the reviewer may be asked to evaluate work done by someone else on a subject of personal interest to himself. In this situation the reviewer and reviewee might well be described as competitors. Furthermore, the reviewer is asked not only to evaluate the author's work but also to provide suggestions for improving it free of charge. Medicine and science appear to be the only areas in which competitors consult one another for free advice. Can you imagine Ford Motor Company asking General Motors Corporation to provide suggestions for improving the quality of a newly designed automobile—without remuneration? Occasionally a reviewer may be asked to evaluate the manuscript of an author for whom he has no fondness, either for professional or personal reasons, or conversely, to evaluate the manuscript of an author for whom he has a high personal regard. In either of these cases the reviewer may be less than objective and the review less than ideal.

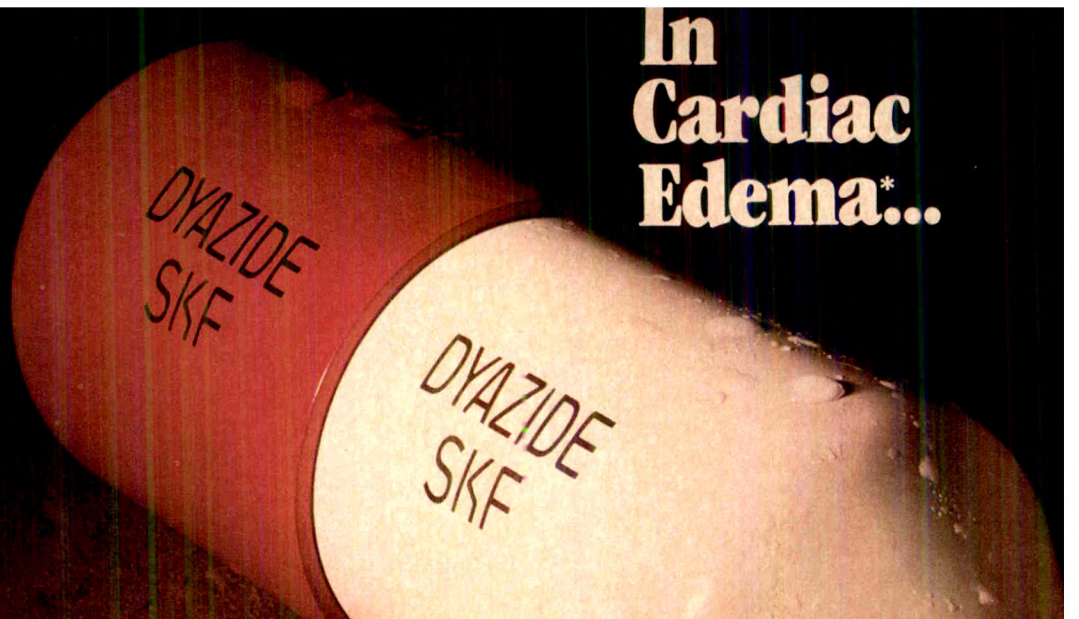
Detecting prejudice (conscious or otherwise) in a review is a continuing challenge for an editor. To help meet this challenge, I have requested that authors submitting manuscripts to the *AJC* (see the *From the Editor* column, July 1982 issue, page A3) provide in the covering letter names of potentially objective and nonobjective reviewers so that predictable or possible conflicts might be avoided.

In this professionally competitive and human atmosphere in which we all reside, the consistently objective reviewer deserves our appreciation and admiration.

William C. Roberts

William C. Roberts, MD
Editor-in-Chief

In Cardiac Edema*...



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

When You Need to Conserve K^+

SK&F CO.
a SmithKline company
Carolina, P.R. 00630

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone; restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

Superior documentation for insomnia in cardiovascular patients

Involving 865 hospitalized patients with cardiovascular conditions

Arteriosclerosis. Hypertension. Congestive heart failure. Myocardial infarction. Cardiac ischemia. Angina pectoris. In these and other cardiovascular conditions, insomnia is frequently a concomitant problem. While primary therapy for the medical condition is paramount, a specific hypnotic to help the patient sleep may be desirable. When needed, the hypnotic most often selected by physicians is Dalmane (flurazepam HCl/Roche).

Copyright © 1982 by Roche Products Inc. All rights reserved.

ROCHE®

In clinical trials, Dalmane was used to induce and maintain sleep in 865 insomniacs with concurrent cardiovascular disease.[1] In addition, a retrospective analysis of Dalmane use in 2542 hospitalized patients, 28% (over 700) of whom were admitted for treatment of cardiovascular disease, showed that Dalmane is an effective hypnotic to use in cardiovascular patients. The vast majority of patients treated with Dalmane showed a satisfactory response.[2] To preclude the risk of oversedation, dizziness and/or ataxia, dosage should be limited to 15 mg in elderly or debilitated patients.

Low incidence of morning hangover

Only 3.1% of all 2542 patients had an adverse reaction to Dalmane—the most frequent being drowsiness, confusion or ataxia.[2] (For other side effects that may occur, see Adverse Reactions in complete product information.) Caution patients about driving, operating hazardous machinery or drinking alcohol during therapy.

Patients slept sooner, longer and through the night—with no reports of rebound insomnia

Objective sleep laboratory studies have consistently demonstrated the efficacy of Dalmane in insomnia. In 8 of 8 studies Dalmane significantly reduced sleep latency in insomniacs. In 6 of 7 studies Dalmane significantly reduced wake time after sleep onset and in 5 of 6 studies Dalmane significantly reduced the number of nocturnal awakenings. Total sleep time increased significantly in 5 of 6 studies, and there were no reports of rebound insomnia, a significant worsening of insomnia after therapy discontinues.[3]

No interference with chronic warfarin therapy or chemical interference with routine laboratory tests

Dalmane does not cause an unacceptable fluctuation in prothrombin time, so it can be used safely in patients on oral anticoagulant therapy (warfarin).[4] And Dalmane does not chemically interfere with results of 22 routine laboratory tests—including SGOT, BUN, creatinine, triglycerides, cholesterol, uric acid, glucose, etc.[5] (See Adverse Reactions for alterations due to pharmacological interference.)

For documented efficacy...

Dalmane® (IV)

flurazepam HCl/Roche

15-mg/30-mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended. Repeated therapy should only be undertaken with appropriate patient evaluation.

Contraindications: Known hypersensitivity to flurazepam HCl; pregnancy. Benzodiazepines may cause fetal damage when administered during pregnancy. Several studies suggest an increased risk of congenital malformations associated with benzodiazepine use during the first trimester. Warn patients of the potential risks to the fetus should the possibility of becoming pregnant exist while receiving flurazepam. Instruct patient to discontinue drug prior to becoming pregnant. Consider the possibility of pregnancy prior to instituting therapy.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. An additive effect may occur if alcohol is consumed the day following use for nighttime sedation. This potential may exist for several days following discontinuation. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Potential impairment of performance of such activities may occur the day following ingestion. Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, abrupt discontinuation should be avoided with gradual tapering of dosage for those patients on medication for a prolonged period of time. Use caution in administering to addiction-prone individuals or those who might increase dosage.

Precautions: In elderly and debilitated patients, it is recommended that the dosage be limited to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in severely depressed patients, or in those with latent depression or suicidal tendencies, or in those with impaired renal or hepatic function.

Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, and elevated SGOT, SGPT, total and direct bilirubins, and alkaline phosphatase; and paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity.

Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg recommended initially until response is determined.

Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

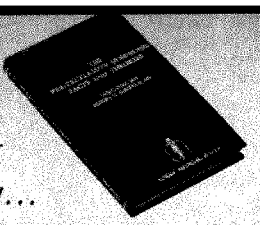
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

CORRECTION

In the September issue on page 475 (Gang ES, Bigger JT Jr, Livelli FD Jr: A Model of Chronic Ischemic Arrhythmias: The Relation Between Electrically Inducible Ventricular Tachycardia, Ventricular Fibrillation Threshold and Myocardial Infarct Size), the first sentence should read as follows: "Stimulation was limited to the right ventricle, a site from which most (80 to 90 percent) ventricular tachycardias can be induced in the clinical setting of a previous myocardial infarction.[5]"

Baseline anginal therapy simplified

Approximately 75% of angina patients were successfully controlled on the starting dosage—one Transderm-Nitro 5

Once-daily application of Transderm-Nitro was shown to provide effective 24-hour baseline therapy in the step-care approach to angina in a survey* of over 1,000 physicians with more than 10,000 patients under treatment.

Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

For full details, please see the Prescribing Information on the next page.

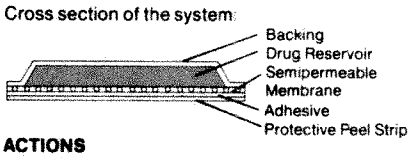
Transderm®-Nitro (nitroglycerin)
Transdermal Therapeutic System

DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring. In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

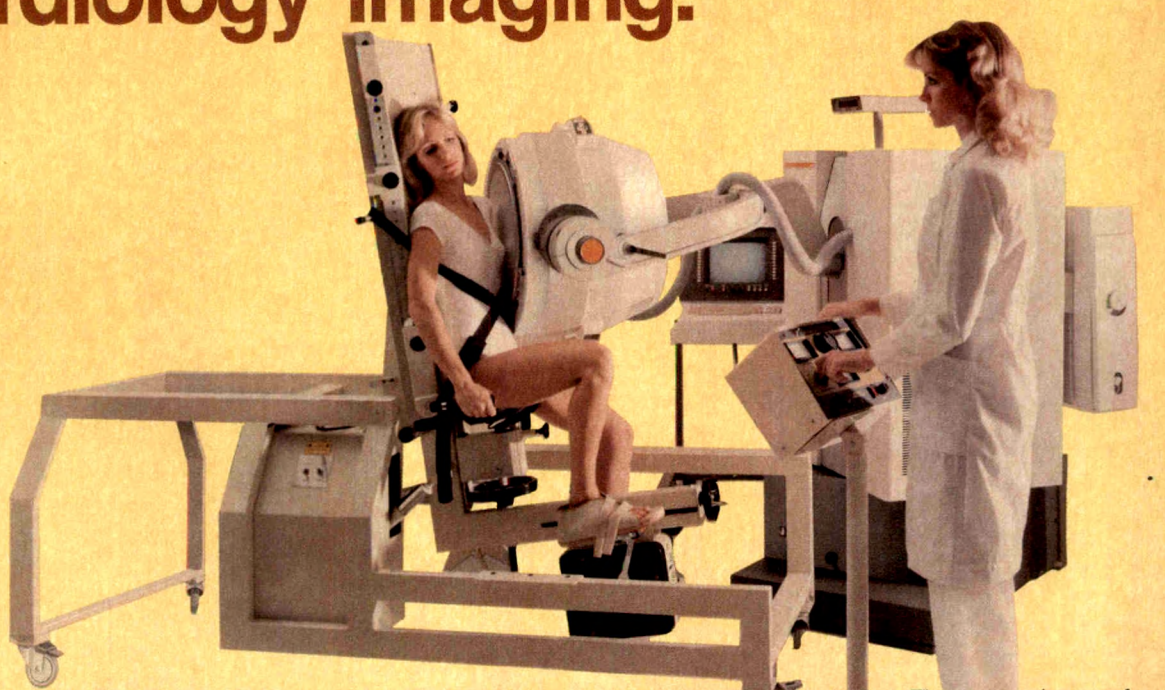
SIEMENS

ZLC and expanded count rate...for reliable nuclear cardiology imaging.



Siemens ZLC 370/750 camera series and lightweight LEM (Low Energy Mobile) system provide you with both the performance and high count rate capability required for dynamic cardiology studies—without loss of image integrity.

The detector arrangement and design of our expanded count rate ZLC 370/750 camera series affords fast and easy patient positioning in demanding stress test examinations. It is also ideally suited for conventional imaging and whole body studies and is easily upgraded for SPECT.

Our LEM system—now featuring ZLC detectors—improves the overall efficiency of bedside cardiology studies. The convenience of a mobile camera is combined with uncompromised image integrity, even in studies demanding expanded count rate.

To maximize your investment, all Siemens systems are offered with comprehensive service programs backed by one of the industry's largest technical service organizations dedicated to nuclear medicine. For additional information on Siemens nuclear imaging systems, contact your local representative or:

Siemens Medical Systems, Inc.

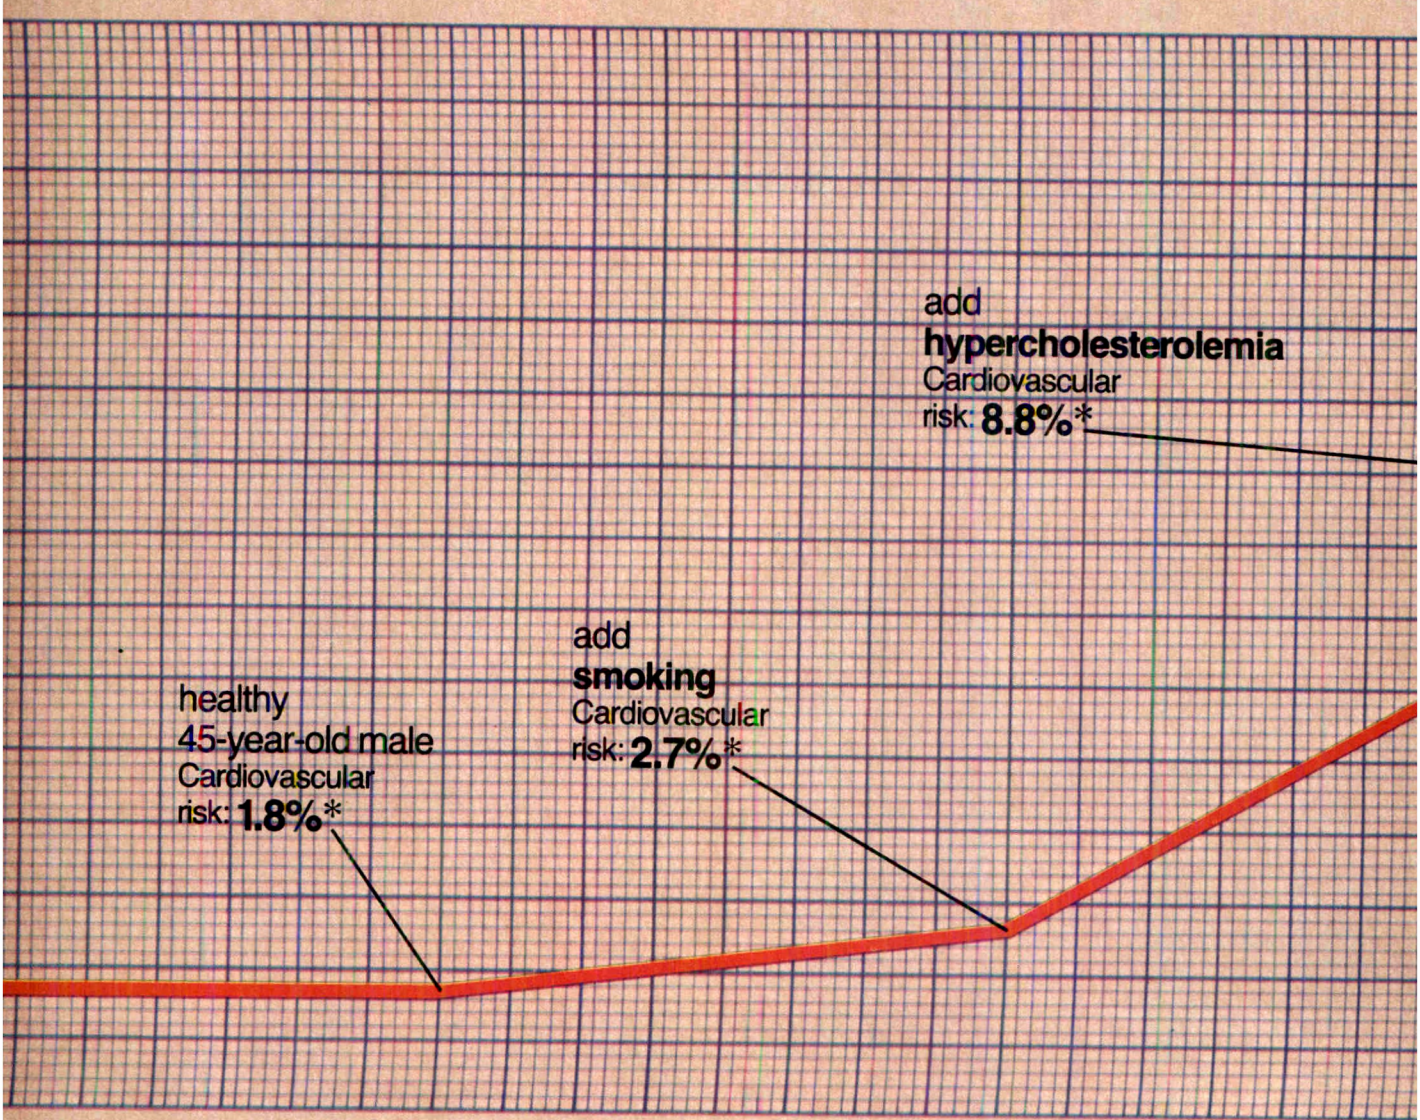
Meeting your diagnostic requirements...into the future.

MGI5310-017 SIQ 327

In hypertensive patients:

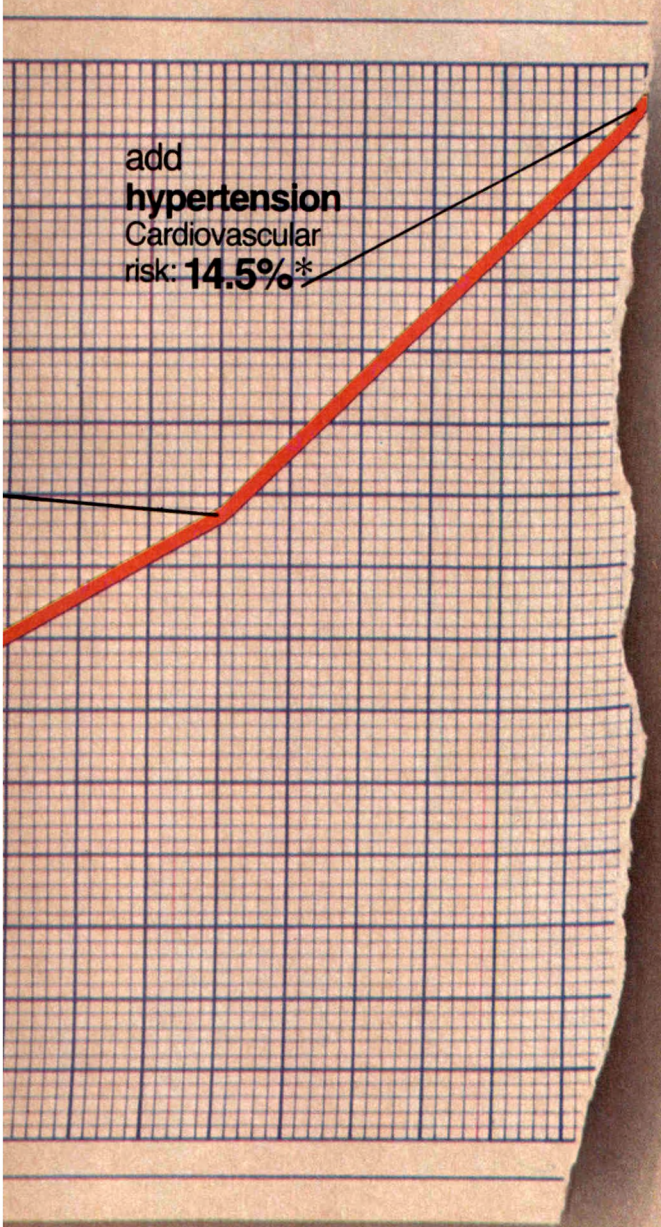


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1mg 2mg 5mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

The ECG cartridge with 50 lives.

Special offer at AHA Exhibit, Booth H-22

DEL MAR AVIONICS

Conventional 24-hour Holter reel tapes have less than 9 lives. And cassettes are recommended only for single use.

But our advanced design, four-channel cartridge, when used with the Series 449 Electrocardiocorder® systems, may be erased and re-used for up to 50 ambulatory recordings.

The reasons?

The cartridge has been specifically designed with extended tape life in mind. Combining the convenience of a cassette with the accuracy of a reel-to-reel design, the cartridge tape can be manipulated at today's high scanning speeds with exact precision. Moreover, precise data management can be attained without tape stretching or twisting, increasing tape life at least ten-fold.

Precise time coding, using a proprietary digital encoding process, ensures timing accuracy to within one second throughout the entire 24-hour recording. And the magnetic characteristics of the tape itself are matched exactly to the dynamic range of our analyzers. Total system compatibility gives you optimal fidelity.

And if that's not enough, one of the cartridge channels can be used to record ambulatory blood pressure, further extending your diagnostic capability.

For more details on the four-channel cartridge that gives you added life, superior fidelity and BP capability, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

CLINICAL STUDIES

933 Intracoronary Thrombolysis in Acute Myocardial Infarction: Duration of Ischemia as a Major Determinant of Late Results After Recanalization

FRANZ SCHWARZ, GERHARD SCHULER, HUGO KATUS, MANFRED HOFMANN, JOACHIM MANTHEY, HARALD TILLMANNS, HELMUTH C. MEHMEL, and WOLFGANG KÜBLER

The effect of the duration of myocardial ischemia on the late results after successful thrombolysis was assessed in 39 patients with acute transmural myocardial infarction. Patients with successful recanalization of the infarct vessel and a time lag between onset of symptoms and reperfusion less than 4 hours were assembled in group A1, and patients with recanalization but a time lag of more than 4 hours comprised group A2. Group B consisted of patients with unsuccessful thrombolysis. Before intervention the groups were comparable with regard to Gensini score of infarct vessel, regional ejection fraction of infarct area, and serum creatine kinase activity. Four weeks after the intervention patients in group A1 had a higher regional ejection fraction of infarct area than patients in groups A2 and B. Peak serum creatine kinase activity was lower in group A1 than in groups A2 and B. Thus, infarct size was reduced after early as compared with late reperfusion.

938 Sulfinpyrazone Decreases Epinephrine-Induced Platelet Aggregation After Myocardial Infarction

JEAN-GILLES LATOUR, PIERRE THEROUX, and MARTIAL G. BOURASSA

Platelet studies were performed during the course of a controlled randomized double-blind clinical trial of sulfinpyrazone in 41 patients who had a recent myocardial infarction. Aggregation of platelet-rich plasma by thrombin, collagen, adenosine diphosphate, and adrenaline was estimated 2 weeks after myocardial infarction and 6, 12, and 24 months later. At the last visit, washed platelet suspensions were also tested for aggregation to thrombin (± epinephrine) and the production of malonyldialdehyde estimated. A reduction (50%, $p < 0.02$) of the aggregation of platelet-rich plasma to epinephrine and a milder ($p < 0.01$) potentiation by the catecholamine of aggregation by thrombin of the washed platelet suspensions were found in the group treated with sulfinpyrazone as compared with the placebo group. Other assays were not useful in discriminating between the 2 groups. It is concluded that sulfinpyrazone (200 mg 4 times daily) normalizes the platelet response to epinephrine.

945 Familial Aggregation of Coronary Heart Disease and Its Relation to Known Genetic Risk Factors

LEO P. ten KATE, HELGE BOMAN, STEPHEN P. DAIGER, and ARNO G. MOTULSKY

Familial aggregation of coronary heart disease in the Pacific Northwest could not be explained by familial clustering of known genetic risk factors such as hypertension, hyperlipidemia, and diabetes. In families with coronary heart disease the risk of myocardial infarction was still twice that of control subjects after statistical manipulation had eliminated the role of these genetic factors. Such unexplained familial aggregation could be caused by various shared environmental factors, by yet undefined genetic factors, or by interaction of unspecified genes with the environment.

954 Assessment of Vasodilator Therapy in Patients With Severe Congestive Heart Failure: Limitations of Measurements of Left Ventricular Ejection Fraction and Volumes

BRIAN G. FIRTH, GREGORY J. DEHMER, ROY V. MARKHAM, Jr., JAMES T. WILLERSON, and L. DAVID HILLIS

This study was performed to assess the relation between changes in left ventricular (LV) volumes and ejection fraction (determined scintigraphically) and changes in intracardiac pressures and forward cardiac index (by thermodilution) in response to administration of sodium nitroprusside in 12 patients with severe, chronic congestive

DEL MAR AVIONICS

For more than 20 years, we've provided cardiologists with the most advanced Holter monitoring data analysis systems in the world.

Now we're extending that experience to ultrasound imaging by offering the Model 8000 Sector Imager™ Echocardiography System.

Priced under $50,000, this complete echocardiography system provides optimum performance from your capital equipment budget.

For example, you get high-resolution, digitally enhanced images. Simultaneous 2-D and M-Mode displays. Variable sector angles of 30, 60, or 90 degrees to increase clinical versatility, as well as A-Mode display with Time Gain Compensation. Plus many more features.

The Sector Imager System is also simple to use. Logically arranged controls enhance operator efficiency. Large diameter wheels provide easy mobility throughout the hospital, office or clinic. And a unique transducer design permits easy access to all acoustical windows.

Data management is further extended by a multi-speed fiber optic recorder and built-in VTR which adds post processing capability in either sector or rectilinear formats.

Most importantly, our Sector Imager System is supported by more than 35 service offices nationwide. So the same factory-trained specialists who support your Holter data analysis equipment can now service your echocardiography systems as well.

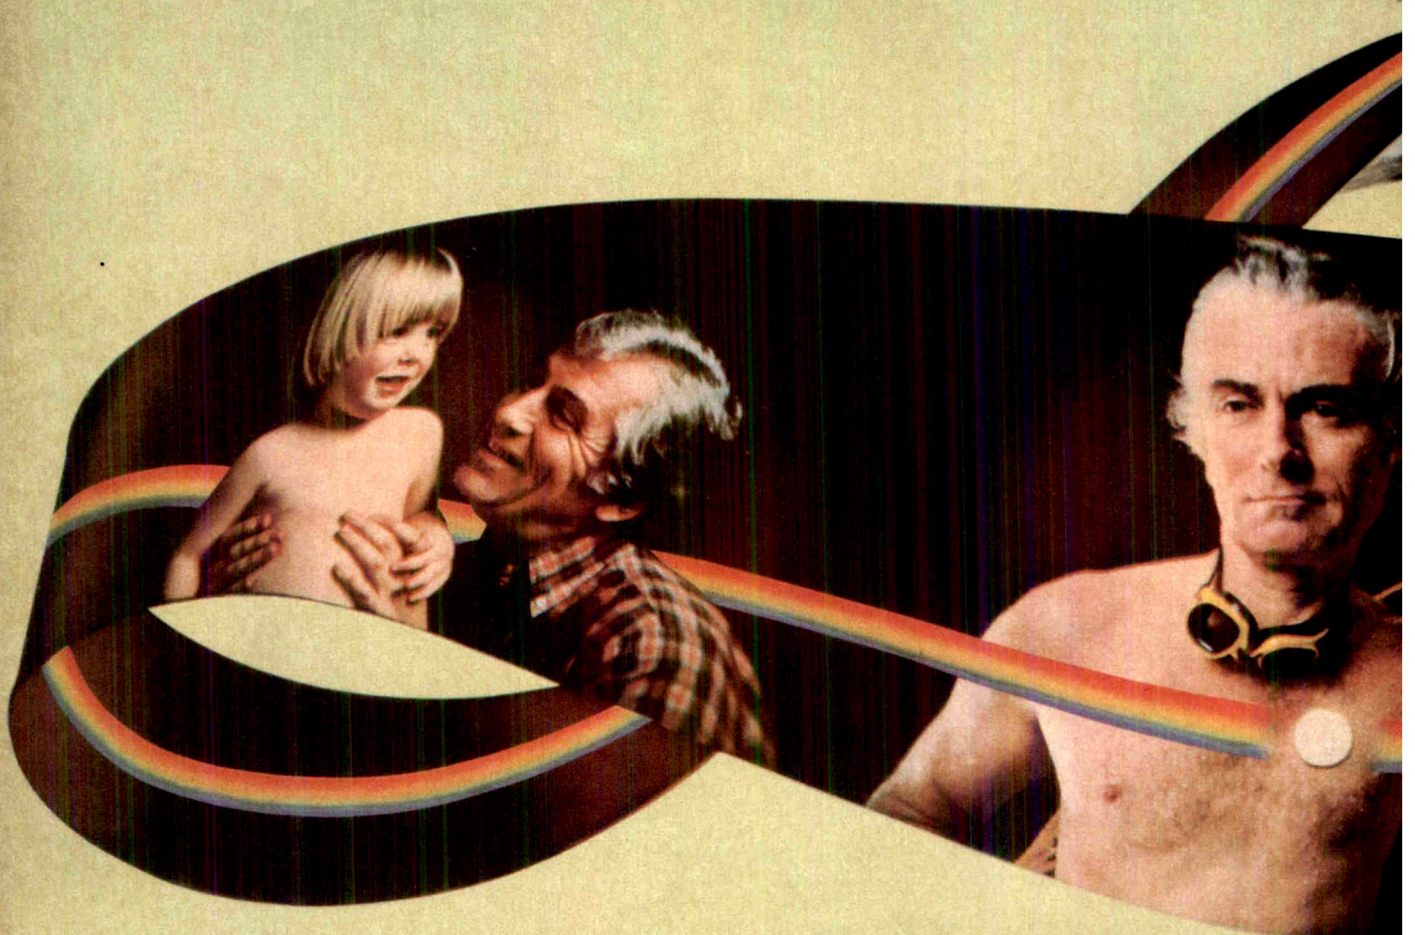
For more details on the echocardiography system that's surprisingly affordable, request Bulletin 8000 from Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714. Telephone 714/549-1500 Telex 68-5621.

SECTOR IMAGER is a trademark, Del Mar Avionics

NITRODISC™

(nitroglycerin) 5-MG/24-HR; 10-MG/24-HR PAD

Continuous anginal



Contraindications for nitroglycerin include patients with increased intraocular pressure. Side effects include headache, hypotension, flushing, and dizziness. In terminating treatment, both the dosage and frequency of application must be gradually reduced during a period of four to six weeks.

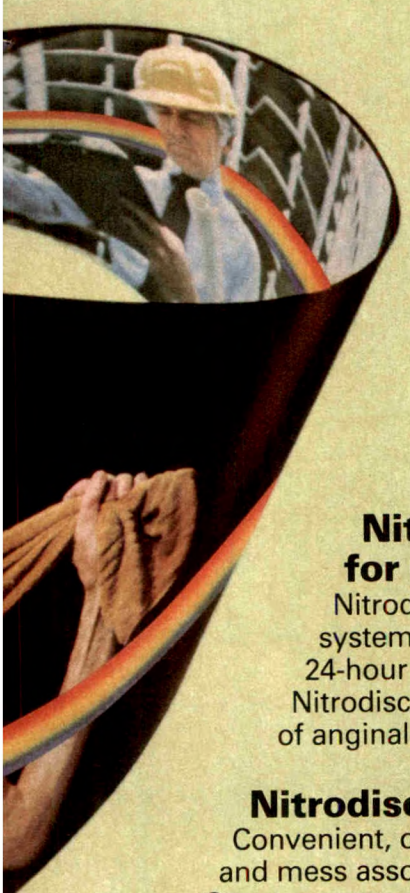
protection...q.d.

Preliminary results from a clinical study indicate 24-hour improvement in exercise capacity

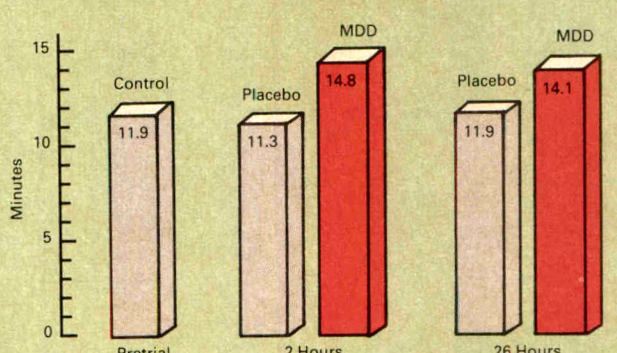
Until now, the clinically recognized benefits of a single nitrate dose have not been documented beyond 12 hours.

In a controlled study,[1] Searle's new nitroglycerin Microseal Drug Delivery™ (MDD) system provided an 18% average increase in exercise capacity 26 hours after application.[2]

In addition, the need for sublingual nitroglycerin was reduced.



Mean Exercise Duration



Nitrodisc (nitroglycerin) eliminates the need for multiple doses of long-acting oral nitrates

Nitrodisc's unique solid polymer releases nitroglycerin into the systemic circulation at a controlled and sustained rate over a 24-hour period.

Nitrodisc (nitroglycerin) is not intended for the immediate relief of anginal attacks.

Nitrodisc enhances compliance

Convenient, once-daily dosage schedule, plus the absence of bother and mess associated with nitroglycerin ointments.

Secure, waterproof adhesive allows for a complete range of daily activities.

1 The interim results presented include data on eight patients completing the protocol to date. A total of twenty patients will be included.

2 Thompson RH: Clinical use of transdermal delivery devices with nitroglycerin. Presented at the Medical Therapy for Angina in the 1980s: New Horizons Symposium, Atlanta, April 24, 1982.

In another clinical study conducted among cardiac rehabilitation participants, concomitant Nitrodisc (nitroglycerin) propranolol therapy did not demonstrate a significant improvement over propranolol alone.

Please see the following page for the complete prescribing information.

SEARLE

5-MG/24-HR; 10-MG/24-HR

NITRODISC™
(nitroglycerin)

DESCRIPTION: The Nitrodisc pad incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths that release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface (see HOW SUPPLIED section).

ACTIONS: When a Nitrodisc pad is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart and peripheral vasculature) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is due to a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In addition, a direct effect of nitroglycerin on the coronary vessels is recognized as well.

In clinical studies, transdermal absorption of nitroglycerin from Nitrodisc occurred in a continuous and well-controlled manner for a minimum of 24 hours. Therapeutic plasma levels were attained within 1 hour after the application of the pad and remained in the therapeutic range for 24 hours. Plasma levels of nitroglycerin were still detectable 30 minutes after removal of the system.

The amount of nitroglycerin released (5 mg/24 hr or 10 mg/24 hr) represents the mean absorption rates through skin determined during clinical evaluations. Absorption may vary among individuals.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: A Nitrodisc pad should be applied once each day. To use the pad, follow the instructions on the package. Nitrodisc should be applied to a skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new pad should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller pad, and that the larger pad be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

PATIENT INSTRUCTIONS FOR APPLICATION: These are provided with the product.

HOW SUPPLIED:

Nitrodisc	5 mg/24 hr	10 mg/24 hr
Drug released per 24 hours	5 mg	10 mg
Total drug content	16 mg	32 mg
Drug releasing surface	8 cm^2	16 cm^2

Nitrodisc pads are supplied in cartons of 30. Store at a controlled room temperature of 59°-86°F (15°-30°C). **Do not refrigerate.** Extremes of temperature and humidity should be avoided.

MYOCARDIAL REVASCULARIZATION
MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCK2

Chicago, Illinois

Now in its fourth year of publication, this acclaimed journal brings you vital information on rapid advances in cardiovascular drug research and use. Under the direction of its eminent international Editorial Board, the Journal has achieved worldwide recognition for:

- Comprehensive coverage of all drugs affecting the heart and blood vessels
- Balanced representation of important basic and clinical areas: creation of drugs, mechanisms of action, testing and evaluation, therapeutic effectiveness, metabolism, side effects, and interactions
- Rigorous standards of originality, scientific merit, and reader interest
- Rapid publication of articles
- Periodic supplements on issues of particular interest or complexity.

Join the growing roster of cardiologists who subscribe to *JOURNAL OF CARDIOVASCULAR PHARMACOLOGY*—an invaluable source of timely information on the medical management of heart disease. Subscribe today!

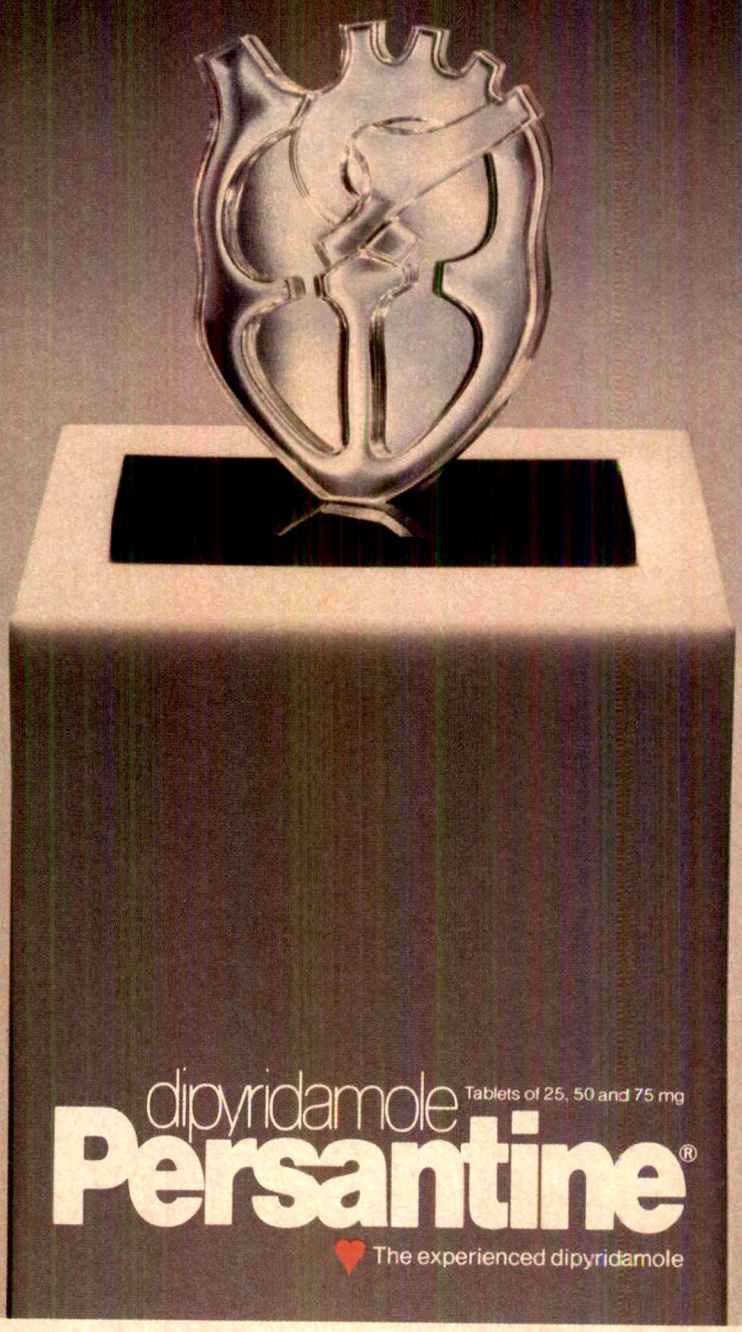
PERSANTINE®
at the heart of the cardiac* revolution



Under a commission from Boehringer Ingelheim Ltd., this striking model of the heart was created by George Giusti, noted sculptor and designer. Mr. Giusti has been awarded no fewer than ten gold and silver medals, and over 80 other awards and citations. His works have been depicted on the covers of such journals as *Fortune, Time* and *Holiday*, and his sculptures are found in the finest collections in this country.

A complimentary replica of "Miroir du Cœur" is available from your Boehringer Ingelheim representative.

*INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows: "Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages.
Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy.
On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

Boehringer Ingelheim
Boehringer Ingelheim Ltd.

heart failure and markedly dilated left ventricles. Nitroprusside caused a decrease in mean systemic arterial, pulmonary arterial, and pulmonary capillary wedge pressures and an increase in the forward cardiac index; simultaneously LV end-diastolic and end-systolic volume indexes decreased. The only significant correlation between scintigraphically and invasively determined variables was between the percent change in the LV end-diastolic volume index and the percent change in pulmonary capillary wedge pressure ($r = 0.68$; $p = 0.01$). Despite this correlation, the percent change in pulmonary capillary wedge pressure was a considerably more sensitive index of the change produced than the percent change in LV end-diastolic volume index.

960 Effects of Acute and Chronic Minoxidil Administration on Rest and Exercise Hemodynamics and Clinical Status in Patients With Severe, Chronic Heart Failure

MARK NATHAN, STANLEY A. RUBIN, DEIRDRE SIEMIENCZUK, and H.J.C. SWAN

The vasodilator properties of minoxidil were investigated in 10 patients with severe chronic heart failure. Short-term evaluation of resting and exercise hemodynamics showed a 40% increase in resting and a 30% increase in exercise cardiac output due to increases in stroke volume. There was little change in intracardiac pressure or arterial pressure, although marked decreases were noted in a few patients. Systemic vascular resistance decreased in patients receiving minoxidil. Short-term adverse effects included development of unstable angina in 1 patient. Five week follow-up showed substantial clinical improvement in 5 patients. However, peripheral edema developed in all patients; even an increase in diuretic drugs did not satisfactorily control edema in all patients. Minoxidil may be a useful afterload reduction agent in some patients with heart failure. Well-known side effects in outpatients may limit its utility.

967 Coronary Hemodynamic Effects of Angiotensin Inhibition by Captopril and Teprotide in Patients With Congestive Heart Failure

JONATHAN L. HALPERIN, DAVID P. FAXON, MARK A. CREAGER, THEODORE A. BASS, CAROLINE D. MELIDOSSIAN, HARALAMBOS GAVRAS, and THOMAS J. RYAN

The coronary hemodynamic effects of vasodilator therapy with angiotensin converting enzyme inhibitors were studied in patients with ischemic heart disease and severe congestive failure. Coronary sinus thermodilution blood flow paralleled perfusion pressure but did not significantly vary overall, and coronary vascular resistance was unchanged. Although the left ventricular stroke-work index rose slightly there was no change in the coronary arteriovenous oxygen content difference or the calculated myocardial oxygen consumption. The heart rate-systolic blood pressure product declined significantly during this period; this relief of cardiac effort was a function of the pretreatment plasma renin activity. A derived index of external myocardial efficiency improved 37%, reflecting greater left ventricular work without increased oxygen demand. Enhancement of myocardial performance after converting enzyme inhibition appears dependent on reduction of angiotensin-mediated ventricular afterload and preload. The lack of coronary vasomotor effects in patients with advanced ischemic cardiomyopathy may reflect limited coronary vascular reserve. Improvement of heart failure in these patients developed without evidence of myocardial ischemia, since balance was maintained between oxygen supply and demand.

973 Accuracy of Cardiac Output, Oxygen Uptake, and Arteriovenous Oxygen Difference at Rest, During Exercise, and After Vasodilator Therapy in Patients With Severe, Chronic Heart Failure

STANLEY RUBIN, DEIRDRE SIEMIENCZUK, MARK D. NATHAN, JOANN PRAUSE, and H.J.C. SWAN

Measurement of hemodynamic and gas exchange variables may be subject to technical and biologic inaccuracies in patients with heart failure. Cardiac output was measured by thermodilution, oxygen uptake by expired gas collection, and arteriovenous oxygen content difference by spectrophotometry in 16 patients with heart failure at rest and during exercise and again after vasodilator therapy. Measured values were compared with values calculated from Fick's principle; excellent correlations were found for cardiac output (r 0.86 to 0.93), for oxygen uptake (r 0.84 to 0.95), and for arteriovenous oxygen difference (r 0.76 to 0.93). It is concluded that no substantial or systematic difference exists between directly measured and calculated values of these variables in patients with heart failure.

979 Effects of Amyl Nitrite on Left Ventricular Relaxation in Patients With Borderline Hypertension

CHARLES Z. NAGGAR, KENNETH STANLEY, and LORI L. DOWNING

Left ventricular relaxation velocity was measured echocardiographically in 22 healthy volunteers and 15 patients with borderline hypertension. The tangent to the left ventricular posterior wall endocardium was measured in diastole and normalized for end-diastolic dimension. This normalized velocity of relaxation at rest was similar

Whatever your patient sets his mind to, Enertrax sets its pace to.

ntroducing Enertrax:
he smallest, most programmable physiologic acemaker, with the useful followup you want.

ou want your patient with a ealthy sinus node to lead a life mited only by his imagination, ot by his pacemaker. He can do it ith Medtronic's completely pro- ammable Enertrax, the most ysiologic pacemaker available.

Whether he's running, reading, anything in between, Enertrax tomatically tracks the patient's rial activity and then paces the ntricle in response when AV nduction fails and no R-wave is nsed. It is the finest replacement r the heart's AV node and Bundle His.

Designed expressly for atrial nchronous, ventricular inhibited DD) pacing, Enertrax can sig- ificantly increase work capacity ver ventricular demand (VVI) acing, permitting normal ranges heart rate as the patient's body irects. Your patient may feel fewer mptoms, have improved well be- g and other proven benefits of DD pacing. All in only 40 grams. nertrax is ideal for a child's grow- g life. It can give both young and lder patients a hemodynamic oost that restores vitality.

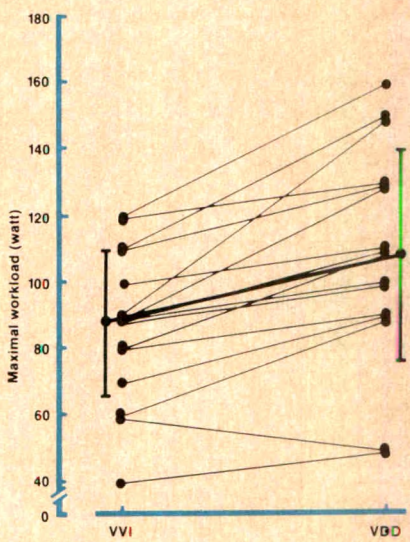
You can easily treat complications such as loss of atrial sensing by reprogramming atrial sensitivity.

Precise, simple patient management. Medtronic technology brings you the simplest and most useful followup tools, a whole performance-matched system. Special telemetry features make Enertrax functions easy to follow while simplifying management for both you and the patient.

Telemetry and programmable functions are controlled by the Medtronic Censys™ programmer, your vital communications link to any Medtronic pacemaker. With Censys and Enertrax, you get a real time "self-diagnostic" marker of pacemaker activity which simplifies follow-up and troubleshooting diagnosis. You also have a real-time calibration pulse and control of eight programmed parameter values. Plus battery status, pacemaker model ID number and many other patient management features.

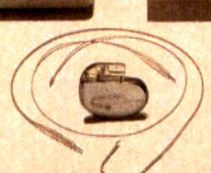
Teletrace telephone monitoring offers you parameter and battery status telemetry, as well as transtelephonic EKG transmission.

VDD pacing provided a 24% increase over VVI pacing in work capacity studies.[1]



For physiologic pacing as individual as each patient's natural heart rate: Enertrax.

For more details on the Enertrax physiologic pacemaker, phone 1-800-328-2518.



Medtronic

Leading the way to man's heart.

1. This particular study was conducted by physicians Ib Kruse and Lars Ryden, Central Hospital, Skövde, Sweden.

ENERTRAX™ Model 7100

Intended Uses
Atrial synchronous pacing using an implantable VDD pacemaker is for patients who have intermittent or complete atrioventricular block with normal sinus activity and who would benefit from regular atrial contribution to ventricular filling and rate variation based on physiologic need.

Contraindications
There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician. Use of the VDD mode is contraindicated in the presence of atrial bradycardias (sick sinus syndrome, sinus arrest), atrial fibrillation, atrial flutter or atrial tachycardias. It is also contraindicated in slow retrograde conduction situations resulting in atrial activity that retriggers the pacemaker.

Warnings
Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions
The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects
Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

William C. Roberts, M.D.
Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.

Dean T. Mason, M.D.
Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California

Mary Allen Engle, M.D.
Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

in both groups. However, the normalized velocity of relaxation in the borderline hypertensive group showed a blunted response to amyl nitrite when compared with that in the normal group. Heart rate, mean arterial pressure, and fractional shortening were the best predictors of normalized velocity of relaxation. Normalized velocity of relaxation may show the earliest measurable change of myocardial dysfunction before alteration in mass or contractility are evident. The echocardiographic amyl nitrite test may prove to be a simple noninvasive tool for the detection of early involvement of cardiac muscle in hypertension.

985 Significance of Abnormal Electrocardiograms in Highly Trained Athletes

DAVID G. OAKLEY and CELIA M. OAKLEY

Electrocardiographic and other abnormalities of highly trained athletes are well recorded but not well enough known, and the more extreme changes still cause diagnostic confusion. This problem was exemplified by 10 athletes, all referred to us by cardiologists because of a diagnosis of organic heart disease. After thorough investigation, including catheter studies, all but 1 of these patients was regarded as normal and all returned to competitive sports. The criteria for diagnosing heart disease in athletes are discussed in light of the findings in these 10 patients. Exercise electrocardiography and echocardiography help to exclude organic disease, but left heart catheterization is justified when doubt still exists.

990 Nonobstructive Hypertrophic Cardiomyopathy: A Precise Assessment of Hemodynamic Characteristics and Clinical Implications

YUZO HIROTA, KOICHI FURUBAYASHI, KIYOTAKA KAKU, GEN SHIMIZU, MASAYA KINO, KEISHIRO KAWAMURA, and TADASU TAKATSU

A precise assessment of left ventricular function was performed in 20 patients with hypertrophic nonobstructive cardiomyopathy to elucidate the basic pathophysiology, and the data were compared with those in 22 normal subjects. Whereas end-diastolic pressure was high in those with cardiomyopathy, a more accurate index of preload, end-diastolic stress, did not differ from normal. Afterload was about half the normal value. Both isovolumic and ejection phase indexes of contractility were in the normal range; however, the end-systolic stress volume ratio was significantly reduced. Although the left ventricular minute work index was in the normal range, the unit muscle performance was very low. An abnormality of left ventricular relaxation was demonstrated by low peak negative dP/dt and prolonged time constant T, and a stiff left ventricle was demonstrated by a high diastolic elastic stiffness constant. These observations suggest that the contraction of a unit muscle is inappropriate to produce an adequate contraction of the whole ventricle, and that hypertrophy might be an adaptive process to maintain normal systolic function by increasing mass and reducing afterload.

998 The Heart and Cardiac Conducting System in Polymyositis-Dermatomyositis: A Clinicopathologic Study of 16 Autopsied Patients

HELEN M. HAUPT, and GROVER M. HUTCHINS

Sixteen autopsied patients with polymyositis-dermatomyositis syndromes were reviewed to determine the nature of the cardiac involvement. The adult patients were aged 32 to 84 years (average 56). There were 2 children, aged 2 and 10 years. Seven patients had congestive heart failure; 4 of these had myocarditis. Two patients had bundle branch block; 1 had myocarditis involving the conduction system. There was active myocarditis in 4 (25%), myocardial fibrosis in 4 (25%), coronary vascular changes in 5 (31%). All patients with active myocarditis had skeletal muscle involvement; 9 patients with myositis did not have myocarditis. There was no correlation of overall severity of disease with active myocarditis. The study shows that cardiac involvement may be common in polymyositis; congestive failure or conduction abnormalities arising in this setting may indicate myocarditis.

1007 Immune Reactions in Tuberculous and Chronic Constrictive Pericarditis. Clinical Data and Diagnostic Significance of Antimyocardial Antibodies

BERNHARD MAISCH, STEFANIE MAISCH, and KURT KOCHSIEK

In all patients with exudative tuberculous pericarditis (n = 12) and viral perimyocarditis (n = 10) antimyolemmal antibodies, a subtype of antisarcolemmal antibodies, were found, whereas this antibody could not be detected in patients with exudative tuberculosis of the lungs and in only 1 of the patients (n = 12) with constrictive pericarditis. Antifibrillary antibodies of the antimyosin type were missed in patients with viral heart disease but could be demonstrated in 75% of patients with tuberculous pericarditis. Sera containing high titer antimyolemmal antibodies induced cytolysis of vital adult heterologous cardiocytes, suggesting that these antibodies are both of diagnostic and pathogenetic relevance.

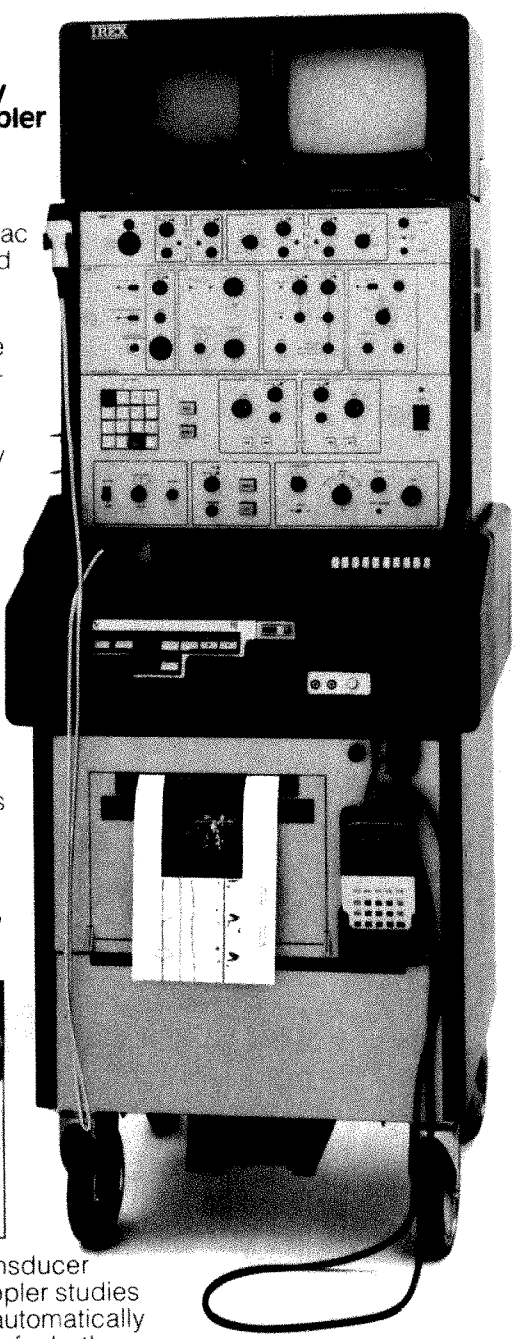
IREX

The Irex Phased Array Real Time Imaging System

SIMULTANEOUS DOPPLER: A NEW DIMENSION IN CARDIAC IMAGING



Simultaneous 2-D phased array imaging and CW or pulsed Doppler for noninvasive correlation of hemodynamics and anatomy

Provides two complementary techniques—2-D to delineate cardiac structure, Doppler to evaluate blood flow velocity patterns—for global assessment of cardiac function.

You can noninvasively measure pressure gradients across obstructions and shunts, quantify relative cardiac output changes, and map flow patterns. Simultaneous display facilitates rapid examinations and permits accurate Doppler sample volume placement.

Combined CW and pulsed Doppler for comprehensive flow measurements

CW Doppler furnishes accurate measurements of high blood flow velocities, while pulsed Doppler provides precise sample location. Versatile spectrum analysis characterizes flow velocity patterns and verifies quality of the Doppler examination.

Simultaneous 2-D/Doppler with one small dual-frequency transducer

A single, small, lightweight transducer permits simultaneous 2-D and Doppler studies through all cardiac windows, and automatically optimizes the ultrasound frequency for both study modalities. Its extremely light, flexible cable permits easy angulation and lessens operator fatigue.

Complete simultaneous documentation of all measurements

Documentation is provided on videotape and superb quality Irex hard copy. This includes: videotapes of 2-D images and localized Doppler sample volume with Doppler audio signal; hard copy recordings of maximum and mean velocity traces; grey scale recordings of Doppler spectrum analysis and gated 2-D image depicting localized Doppler sample; time correlated with other data traces including ECG, phono, and pulse.

Simultaneous phased array 2-D and superior dual derived M-modes

In addition, you get fully diagnostic ECG, with 12 selectable leads; phono with two channels and eight filter settings; and pulse. All data channels are fully synchronized, and all perform simultaneously.

Irex systems provide incomparable value in meeting all your cardiodiagnostic needs. For details on the Irex Phased Array Real Time Imaging System, Irex System II for M-mode studies, 2-D applications, and cath lab applications, and the Irex Cardio 80® general-purpose microcomputer for cardiology, contact us today.

Burroughs Wellcome announces

An oral digoxin with enhanced bioavailability

Absorption of digoxin from LANOXICAPS® is 90-100% complete!

The enhanced digoxin absorption from LANOXICAPS® compared to tablets and elixir is associated with reduced between-patient and within-patient variability in steady-state serum concentrations.

Comparison of bioavailability and equivalent doses				
Product	Bioavailability	Equivalent Doses (in MG)*		
Lanoxin® Tablet	60-80%	0.125	0.25	0.5
Lanoxin® Elixir	70-85%	0.125	0.25	0.5
Lanoxin® Injection/IM	70-85%	0.125	0.25	0.5
Lanoxin® Injection/IV	100%	0.1	0.2	0.4
LANOXICAPS® Capsules	90-100%	0.1	0.2	0.4

*1 mg = 1,000 μg

Due to the more complete absorption of digoxin from Lanoxicaps, recommended oral doses are 80% of those for tablets, elixir, and IM injection.

Lanoxicaps may help make a smoother transition for patients who are being switched from intravenous to oral therapy. Also, consider Lanoxicaps for all your newly diagnosed patients.

Colors of Lanoxicaps are distinctive, for less confusion or misidentification by patients. Please see next page for brief summary of prescribing information.

new LANOXICAPS®
(digoxin solution in capsules)

(digoxin solution in capsules)

LANOXICAPS® brand DIGOXIN SOLUTION IN CAPSULES 50 μg (0.05 mg), 100 μg (0.10 mg), and 200 μg (0.20 mg)
Brief Summary of Prescribing Information

INDICATIONS AND USAGE
Heart Failure: The increased cardiac output resulting from the inotropic action of digoxin ameliorates the disturbances characteristic of heart failure (venous congestion, edema, dyspnea, orthopnea and cardiac asthma).

Digoxin is more effective in "low output" (pump) failure than in "high output" heart failure secondary to arteriovenous fistula, anemia, infection or hyperthyroidism.

Digoxin is usually continued after failure is controlled, unless some known precipitating factor is corrected. Studies have shown, however, that even though hemodynamic effects can be demonstrated in almost all patients, corresponding improvement in the signs and symptoms of heart failure is not necessarily apparent. Therefore, in patients in whom digoxin may be difficult to regulate, or in whom the risk of toxicity may be great (e.g., patients with unstable renal function or whose potassium levels tend to fluctuate) a cautious withdrawal of digoxin may be considered. If digoxin is discontinued, the patient should be regularly monitored for clinical evidence of recurrent heart failure.

CONTRAINDICATIONS
Digitalis glycosides are contraindicated in ventricular fibrillation.

Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin, as is hypersensitivity to digoxin itself. Allergy to digoxin, though rare, does occur. It may not extend to all preparations, and another digitalis glycoside may be tried with caution.

WARNINGS
The use of digoxin or other digitalis glycosides is unwarranted in the treatment of obesity.

Digoxin in soft capsules should be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate.

Anorexia, nausea, vomiting, and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity. Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS
General: Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range," because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B, or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see *Treatment of arrhythmias produced by overdosage*, in OVERDOSAGE section).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the quinidine dose. Because of the considerable variability of this interaction, digoxin dosage should be carefully individualized.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (eg, hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e., sick sinus syndrome), digoxin may worsen sinus bradycardia or sinoatrial block.

In patients with Wolff-Parkinson-White syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

Drug Interactions: Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. *Antacids, kaolin-pectin, sulfasalazine, neomycin,* and *cholestyramine* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias, because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although *propranolol* and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

ADVERSE REACTIONS
The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5% to 20%, with 15% to 20% being considered serious (1% to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

Adults:
Cardiac—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm, and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage.

Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

Gastrointestinal—Anorexia, nausea, vomiting, and, less commonly, diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

CNS—Visual disturbances (blurred or yellow vision), headache, weakness, apathy, and psychosis can occur.

Other—Gynecomastia is occasionally observed.

Infants and Children:
Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea, and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular

arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first-degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

OVERDOSAGE Treatment of arrhythmias produced by overdosage

Adults:

Digoxin should be discontinued until all signs of toxicity are gone. Discontinuation may be all that is necessary if toxic manifestations are not severe.

Potassium salts are commonly used, particularly if hypokalemia is present. Potassium chloride in divided oral doses totaling 3 to 6 grams of the salt (40 to 80 mEq K+) for adults may be given provided renal function is adequate (see below for potassium recommendations in infants and children).

When correction of the arrhythmia is urgent and the serum potassium concentration is low or normal, potassium should be administered intravenously in 5% dextrose injection. For adults, a total of 40 to 80 mEq (diluted to a concentration of 40 mEq per 500 ml) may be given at a rate not exceeding 20 mEq per hour, or slower if limited by pain due to local irritation. Additional amounts may be given if the arrhythmia is uncontrolled and potassium well tolerated. ECG monitoring should be performed to watch for any evidence of potassium toxicity (e.g., peaking of T waves) and to observe the effect on the arrhythmia. The infusion may be stopped when the desired effect is achieved.

Note: Potassium should not be used and may be dangerous in heart block due to digoxin unless primarily related to supraventricular tachycardia.

Other agents that have been used for the treatment of digoxin intoxication include lidocaine, procainamide, propranolol, and phenytoin, although use of the latter must be considered experimental. In advanced heart block, temporary ventricular pacing may be beneficial.

Infants and Children:

See Adults section (immediately above) for general recommendations for the treatment of arrhythmias produced by overdosage and for cautions regarding the use of potassium.

If a potassium preparation is used to treat toxicity, it may be given orally in divided doses totaling 1 to 1.5 mEq K+ per kilogram (kg) body weight (1 gram of potassium chloride contains 13.4 mEq K+).

When correction of the arrhythmia with potassium is urgent, approximately 0.5 mEq/kg of potassium per hour may be given intravenously, with careful ECG monitoring. The intravenous solution of potassium should be dilute enough to avoid local irritation; however, especially in infants, care must be taken to avoid intravenous fluid overload.

DOSAGE AND ADMINISTRATION

Recommended dosages are average values that may require considerable modification because of individual sensitivity or associated conditions. Diminished renal function is the most important factor requiring modification of recommended doses.

Due to the more complete absorption of digoxin from soft capsules, recommended oral doses are only 80% of those for tablets, elixir, and IM injection.

Because the significance of the higher peak serum concentrations associated with once-daily capsules is not established, divided daily dosing is presently recommended for:

1. infants and children under 10 years of age;
2. patients requiring a daily dose of 300 μg (0.3 mg) or greater;
3. patients with a previous history of digitalis toxicity;
4. patients considered likely to become toxic;
5. patients in whom compliance is not a problem.

Where compliance is considered a problem, once-daily dosing may be appropriate.

Adults:

Adults: rapid digitalization with a loading dose—Peak body digoxin stores of 8 to 12 μg/kg should provide therapeutic effect with minimum risk of toxicity in most patients with heart failure and normal sinus rhythm. Larger stores (10 to 15 μg/kg) are often required for adequate control of ventricular rate in patients with atrial flutter or fibrillation. Because of altered digoxin distribution and elimination, projected peak body stores for patients with renal insufficiency should be conservative (i.e., 6 to 10 μg/kg [see PRECAUTIONS section]).

The loading dose should be based on the projected peak body stores and administered in several portions, with roughly half the total given as the first dose. Additional fractions of this planned total dose may be given at 6- to 8-hour intervals, *with careful assessment of clinical response before each additional dose.*

If the patient's clinical response necessitates a change from the calculated dose of digoxin, then calculation of the maintenance dose should be based upon the amount actually given.

Dosage for Previously Undigitalized Patients:

In previously undigitalized patients, a single initial Lanoxicaps dose of 400 to 600 μg (0.4 to 0.6 mg) usually produces a detectable effect in 0.5 to 2 hours that becomes maximal in 2 to 6 hours. Additional doses of 100 to 300 μg (0.1 to 0.3 mg) may be given cautiously at 6- to 8-hour intervals until clinical evidence of an adequate effect is noted. The usual amount of Lanoxicaps that a 70-kg patient requires to achieve 8 to 15 μg/kg peak body stores is 600 to 1000 μg (0.6 to 1.0 mg).

Adults: gradual digitalization with a maintenance dose—The following table provides average Lanoxicaps daily maintenance dose requirements for patients with heart failure based upon lean body weight and renal function:

Usual Lanoxicaps Daily Maintenance Dose Requirements (μg) for Estimated Peak Body Stores of 10 μg/kg

Corrected Ccr (ml/min per 70 kg)	Lean body weight (kg/lbs) 50/110	60/132	70/154	80/176	90/198	100/220	Number of days before steady-state achieved
0	50	100	100	100	150	150	22
10	100	100	100	150	150	150	19
20	100	100	150	150	150	200	16
30	100	150	150	150	200	200	14
40	100	150	150	200	200	250	13
50	150	150	200	200	250	250	12
60	150	150	200	200	250	300	11
70	150	200	200	250	250	300	10
80	150	200	200	250	300	300	9
90	150	200	250	250	300	350	8
100	200	200	250	300	300	350	7

Example—Based on the above table, a patient in heart failure with an estimated lean body weight of 70 kg and a Ccr of 60 ml/min should be given 200 μg (0.2 mg) of Lanoxicaps per day, usually taken as a 100 μg (0.1 mg) capsule after the morning and evening meals. Steady-state serum concentrations should not be anticipated before 11 days.

Digitalizing Dose for Children:

Usual Digitalizing and Maintenance Dosages for Lanoxicaps in Children With Normal *Renal Function Based on Lean Body Weight*

Age	Digitalizing* Dose (μg/kg)	*Daily*† Maintenance Dose (μg/kg)
2-5 Years	25-35	25%-35% of the oral or IV loading dose‡
5-10 Years	15-30	
Over 10 Years		

*IV digitalizing doses are the same as Lanoxicaps digitalizing doses.

†Divided daily dosing is recommended for children under 10 years of age.

‡Projected or actual digitalizing dose providing desired clinical response.

More gradual digitalization can also be accomplished by beginning an appropriate maintenance dose. The range of percentages provided above can be used in calculating this dose for patients with normal renal function. In children with renal disease, digoxin dosing must be carefully titrated based upon desired clinical response.

Long-term use of digoxin is indicated in many children who have been digitalized for acute heart failure, unless the cause is transient. Children with severe congenital heart disease, even after surgery, may require digoxin for prolonged periods.

It cannot be overemphasized that both the adult and pediatric dosage guidelines provided are based upon average patient response and substantial individual variation can be expected. Accordingly, ultimate dosage selection must be based upon clinical assessment of the patient.

Until December 31st, you'll get an AP-1 Auto Programmer free when you buy our three-channel ExTOL™ exercise tolerance system. And with the new accelerated investment tax credit advantages now available, this free offer makes a Burdick ExTOL system even more attractive.

ExTOL System III includes a three-channel ECG, defibrillator, four-channel monitor, and patient-safe treadmill that interfaces with the auto programmer for precise control of speed and elevation functions, plus ECG start and stop control.

This coordinated ExTOL system gives you and your medical team the ability to concentrate on monitoring your patient throughout the procedure.

Get a free sequencing timer with our single-channel ExTOL system.

Designed for the lighter workloads of smaller clinics and practices, our ExTOL System I fills the need for compact, economical instrumentation. The system includes a single-channel ECG and monitor, defibrillator, and treadmill. Until December 31st, we'll include our ExT-1 Sequencing Timer at no extra charge. It provides digital display of elapsed time and start/stop control for the ECG.

Call or write to find out more about either offer. The information is free, too.

Our ExTOL automatic programmer lets you concentrate on the patient.

And now it's free.

1014 Constrictive Pericarditis: New Aspects

NOBLE O. FOWLER

The current knowledge of constrictive pericarditis is reviewed briefly. Etiology, physical signs, electrocardiographic findings, hemodynamic features, and angiographic aspects are presented. Recent changes in etiology are discussed. The mechanism of the pericardial knock is elucidated. The fluid challenge procedure is described. The role and limitations of M-mode echocardiography in this disease are highlighted. The value of other noninvasive studies such as measurement of systolic time intervals, myocardial radioisotope scanning, and high-speed echocardiography is described. Emphasis is placed on the invasive and noninvasive methods that may be useful in separating restrictive cardiomyopathy from constrictive pericarditis. There is a brief commentary on the methods of treatment, indications for pericardial resection, and the current operative results.

1018 Echocardiographic Study of Right Ventricular Wall Motion in Cardiac Tamponade

PETER J. ENGEL, HENRY HON, NOBLE O. FOWLER, and SANDI PLUMMER

Twenty-one patients had M-mode echocardiographic recordings during cardiac tamponade. Seventeen of 21 had posterior motion of right ventricular endocardium at 0.05 second or longer after opening of the mitral valve. Sixteen of 17 patients with a large pericardial effusion without cardiac tamponade had posterior right ventricular wall motion that ceased at 0.05 second or less after opening of the mitral valve. The finding of early diastolic posterior motion of the right ventricular wall may signify diastolic collapse of the right ventricle and aids the echocardiographic identification of cardiac tamponade.

1022 Two-Dimensional Echocardiographic Findings in Cardiac Trauma

FLETCHER A. MILLER, Jr., JAMES B. SEWARD, BERNARD J. GERSH, ABDUL J. TAJIK, and PETER MUCHA, Jr.

Cardiac contusion is a potentially fatal complication of blunt chest trauma. The diagnosis is obscured because cardiac contusion usually occurs in a setting of multisystem trauma. Furthermore, the electrocardiographic changes are nonspecific. Experience with 2-dimensional echocardiography in evaluating cardiac trauma has not previously been emphasized. The results of 2-dimensional echocardiography are examined in 7 patients after significant blunt chest trauma. The findings show that 2-dimensional echocardiography is useful for diagnosing cardiac contusion, for estimating the extent of myocardial damage, and for identifying accompanying cardiac lesions such as thrombi, pericardial effusion, and valvular disruption.

1028 Assessment of Left Ventricular Relaxation in Patients With Valvular Regurgitation

MICHEL F. ROUSSEAU, HUBERT POULEUR, ANDRE A. CHARLIER, and LUCIEN A. BRASSEUR

The aim of the study was to assess ventricular relaxation in patients with mitral or aortic regurgitation. The hemodynamic and angiographic data were analyzed during the phase of decreasing left ventricular elastance (that is, when pressure is decreasing while volume is increasing) in 57 patients (27 with valvular regurgitation, 17 normal subjects, and 13 with coronary heart disease). Starting from a fixed level of wall stress (40 kdyne/cm^2), the incremental left ventricular elastance (ratio $\Delta P/\Delta V$) produced by a constant increase in left ventricular volume (+20 ml/m^2) was computed. In aortic and mitral regurgitation, the incremental elastance (−0.52 versus −0.95 mm Hg/ml/m^2 in normal subjects; $p < 0.001$) was abnormal. Significant correlations were found in the entire group between incremental elastance and ejection fraction ($r = 0.63$), and mean velocity of fiber shortening ($r = 0.62$), suggesting a relation between impaired incremental elastance and alterations in inotropic state or afterload, or both.

1037 Detection of Mild Aortic Regurgitation by Range-Gated Pulsed Doppler Echocardiography

RICARDO J. ESPER

To assess the sensitivity and specificity of the range-gated pulsed Doppler echocardiogram for the detection of aortic regurgitation, a study with use of this technique was carried out in 46 patients, classified into 3 groups: Group I was composed of 19 patients with a variety of heart diseases but with a competent aortic valve. Group II was composed of 17 patients who clinically and by auscultation had aortic regurgitation, confirmed by cardiac catheterization in 6. Group III was composed of 10 patients with aortic regurgitation but without the expected clinical or auscultatory evidence. Results show that the Doppler echocardiogram was more useful than ausculta-

Continued on Page A38

tion and echocardiography for the detection of mild aortic regurgitation. In this study the range-gated pulsed Doppler echocardiogram proved 100% sensitive and specific. However, it will be necessary to study larger groups in order to assess its utility in more complicated conditions (obesity, emphysema, and heart failure) and the differential diagnosis with other diastolic murmurs.

1044 Large V Waves in the Pulmonary Wedge Pressure Tracing in the Absence of Mitral Regurgitation

AUGUSTO D. PICHARD, RICHARD KAY, HARRY SMITH, PETER RENTROP, JAMES HOLT, and RICHARD GORLIN

The accurate diagnosis of mitral regurgitation has important therapeutic implications. Large V waves in the pulmonary wedge pressure may be misleading in the diagnosis of mitral regurgitation. Of 237 consecutive patients with high quality hemodynamic, angiographic, and echocardiographic data, 27 had large V waves (peak V 10 mm Hg greater than pulmonary wedge mean pressure). Ventriculograms were analyzed in blind fashion by 3 expert angiographers for any angiographic evidence of mitral regurgitation; 17 patients had mitral regurgitation (group I), and 10 did not (group II). The control group (group III) of 22 patients had normal V waves and no mitral regurgitation. Twenty-two hemodynamic and echocardiographic variables were compared among groups. It is concluded that large V waves in the pulmonary wedge pressure tracing can be seen in the absence of mitral regurgitation. The size of the V wave is related to factors that determine left atrial compliance. Caution is called for in the diagnosis of mitral regurgitation by pulmonary wedge pressure alone.

1051 Pregnancy in Patients With a Porcine Valve Bioprosthesis

UBERTO BORTOLOTTI, ALDO MILANO, ALLESSANDRO MAZZUCCO, CARLO VALFRE, ROSARIO RUSSO, MARIALUISA VALENTE, LUCIANO SCHIVAZAPPA, GAETANO THIENE, and VINCENZO GALLUCCI

Seven patients who became pregnant after valve replacement with a Hancock bioprothesis were followed up during 8 pregnancies. Six had undergone isolated mitral valve replacement, and 1 had mitral and aortic valve replacement. The only major complication during pregnancy was cardiac failure in 1 patient, associated with onset of atrial fibrillation. Results of this study show that (1) bioprosthetic valves can be considered the most suitable devices in women of childbearing age because anticoagulants can be avoided, therefore eliminating the risks related to inappropriate administration of oral anticoagulants as well as the hazards associated with the potential teratogenic effect of coumarin drugs; and (2) pregnancy might favor calcification of porcine heterografts, leading to bioprosthetic failure. Until further data are available to support this suspicion, close clinical and echocardiographic follow-up study of these patients is recommended after pregnancy.

ELECTROPHYSIOLOGIC STUDIES

1055 Electrophysiologic Drug Testing in Patients With Malignant Ventricular Arrhythmias: Importance of Stimulation at More Than 1 Ventricular Site

FRED MORADY, DAVID HESS, and MELVIN M. SCHEINMAN

Sixty-four patients with symptomatic ventricular tachycardia (VT) or ventricular fibrillation (VF) underwent right ventricular apical programmed stimulation and had no inducible VT during drug testing. Thirty patients (Group I) did not undergo left ventricular stimulation. Left ventricular stimulation in 38 drug trials induced no VT in 50% (Group IIA), nonsustained VT in 26% (Group IIB), and sustained VT in 24% (Group IIC). It is concluded that if only right ventricular apical stimulation is performed during electrophysiologic drug testing in patients with malignant ventricular arrhythmias, approximately 50% of drug trials may be incorrectly judged as suppressing the induction of VT. Drug therapy that suppresses VT induction with both right and left ventricular programmed stimulation results in a significantly better clinical response than therapy based on the results of only right ventricular stimulation.

1061 Electrophysiologic Study for Ventricular Arrhythmia: Effect on Total and Myocardial-Specific Creatine Kinase Activity

FRANCIS E. MARCHLINSKI, HARVEY L. WAXMAN, LESLIE M. SHAW, MARILYN D. EZRI, and MARK E. JOSEPHSON

After electrophysiologic study for ventricular arrhythmias, serially measured total creatine kinase enzyme activity was modestly elevated (greater than 2 X baseline or more than normal) at 24 hours in 10 (42%) of the 24 patients studied. However, no patient had an increase in creatine kinase B-subunit enzyme activity despite the need for emergency cardioversion in 9 of 14 patients with sustained ventricular tachycardia or fibrillation induced during electrophysiologic study and despite the presence of coronary heart disease in 14 (58%) of the 24 patients studied.

you prescribe

is

βBLOCADREN®

(TIMOLOL MALEATE | MSD)

nly BLOCADREN is resently indicated for the ost-MI patient to reduce e risk of reinfarction, and LOCADREN is the only eta blocker whose dosage as been established rough extensive clinical als to be the same for ost-MI as for initial therapy hypertension. In ypertension the starting osage is only 10 mg b.i.d. here is only one dosage for rophylactic use in stabilized atients surviving the acute hase of an MI: 10 mg b.i.d.

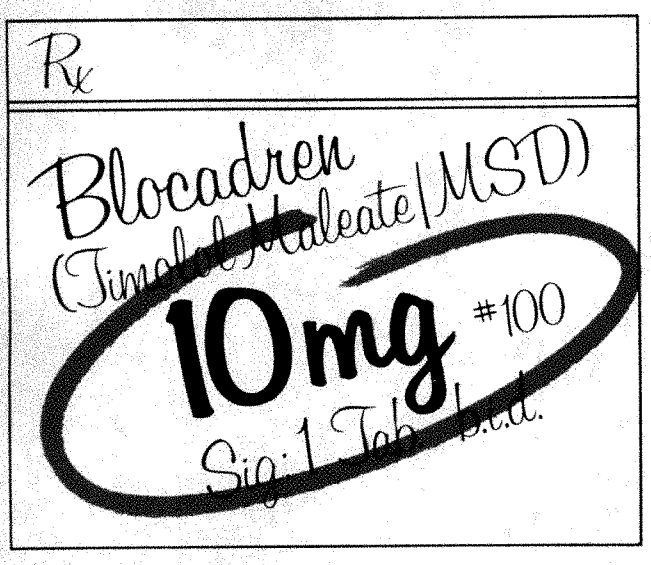
LOCADREN is contraindicated patients with: bronchospasm, cluding bronchial asthma, or vere chronic obstructive lmonary disease; sinus bradycardia; cond- and third-degree rioventricular block; overt cardiac lure (see below); cardiogenic ock; and hypersensitivity to

Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, BLOCADREN should be

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal— Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

for initial therapy in hypertensive patients



Usual dosage range:
10 to 20 mg b.i.d.

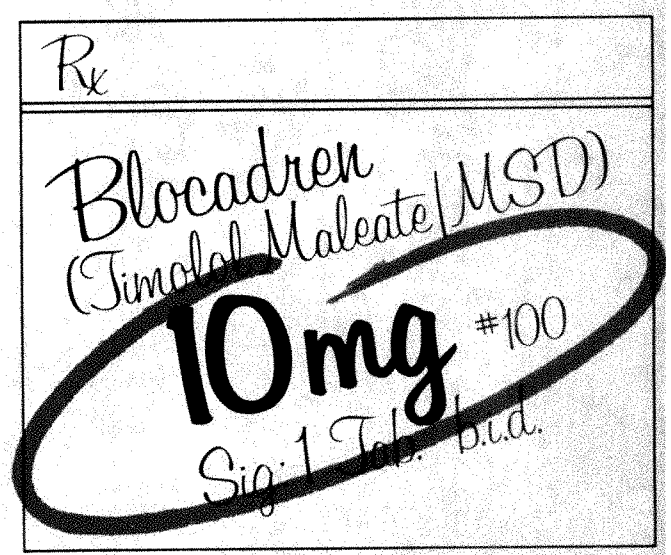
Maximum dosage:
30 mg b.i.d.

There should be an interval of at least seven days between increases in dosages.

Also available:
20-mg tablets

NOTE: IN HYPERTENSION
BLOCADREN may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

for reducing the risk of reinfarction in stabilized post-MI patients



Dosage:
10 mg b.i.d.

Treatment should be initiated within 1 to 4 weeks after infarction.

Data are not available as to whether benefit would ensue if initiated later.

only 10 mg b.i.d.
for initial therapy in hypertension and post-MI

For a Brief Summary of Prescribing Information, please see next page.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n = 176) %	Placebo (n = 168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction*		Withdrawal†	
	Timolol (n = 945) %	Placebo (n = 939) %	Timolol (n = 945) %	Placebo (n = 939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1

Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

*When an adverse reaction recurred in a patient, it is listed only once.

†Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

1066 Amiodarone for Control of Sustained Ventricular Tachyarrhythmia: Clinical and Electrophysiologic Effects in 51 Patients

HARVEY L. WAXMAN, WILLIAM C. GROH, FRANCIS E. MARCHLINSKI, ALFRED E. BUXTON, LAURA M. SADOWSKI, LEONARD N. HOROWITZ, MARK E. JOSEPHSON, and JOHN A. KASTOR

The electrophysiologic effects of amiodarone and its ability to control ventricular arrhythmia were evaluated in a selected group of 51 patients with refractory sustained ventricular arrhythmia. Amiodarone prolonged refractoriness in the atria, atrioventricular (AV) node, and ventricle as well as conduction through the AV node and His-Purkinje system. Although it had no effect on sinus nodal recovery time and sinoatrial conduction time, it prolonged the sinus cycle length and 2 patients required a permanent pacemaker for symptomatic sinus bradycardia. Amiodarone did not alter the ease of VT inducibility in any consistent manner. Its clinical effectiveness could be evaluated in 46 patients. It provided effective therapy in 23, partly effective therapy in 13, and was ineffective in 10. Adverse effects were noted in 28 of 51 patients, and in 11 the drug had to be discontinued. It is concluded that amiodarone is useful for the treatment of refractory sustained ventricular arrhythmia, but its use should be reserved for patients with life-threatening sustained arrhythmia. Good clinical response can be observed in patients receiving amiodarone in spite of continued inducibility.

1075 Lack of Effectiveness of Oral Mexiletine in Patients With Drug-Refractory Paroxysmal Sustained Ventricular Tachycardia. A Study Utilizing Programmed Stimulation

EDWIN V. PALILEO, WILLIAM WELCH, JULIE HOFF, BORIS STRASBERG, ROBERT A. BAUERNFEIND, STEVEN SWIRYN, ALDO COELHO, and KENNETH M. ROSEN

Recent studies indicate that oral administration of mexiletine is useful in the therapy of recurrent ventricular tachycardia (VT). To further define the clinical usefulness of this drug, mexiletine was administered to 13 men and 4 women (mean age 62 years) who had drug-refractory paroxysmal sustained VT. All 17 patients had inducible sustained VT during the control electrophysiologic study and during serial electrophysiologic study on conventional drugs. The 47% incidence of noncardiovascular side effects was similar to that in previous reports, but the 29% incidence of arrhythmia potentiation by mexiletine was unexpectedly higher. Limited follow-up reveals recurrence of VT in 3 of 4 patients treated with oral mexiletine on a long-term basis. It is concluded that oral mexiletine does not appear useful in patients with drug-refractory, paroxysmal sustained VT. In addition, its use is associated with a high incidence of adverse effects, some of which can be serious and life-threatening.

1082 Prolongation of the Human Cardiac Monophasic Action Potential by Sotalol

DEBRA S. ECHT, LARRY E. BERTE, WILLIAM T. CLUSIN, ROLF G. SAMUELSSON, DONALD C. HARRISON, and JAY W. MASON

Sotalol and propranolol are nonselective, beta-blocking agents. Sotalol at a low concentration, unlike propranolol, prolongs the duration of the transmembrane action potential in vitro. In a double-blind study, we compared the electrophysiologic effects of intravenous sotalol (0.30 or 0.60 mg/kg; n = 9) with intravenous propranolol (0.15 or 0.20 mg/kg; n = 8) in 17 patients using bipolar suction electrodes in the right atrium and right ventricle to determine whether sotalol prolongs the monophasic action potential duration in man. After sotalol administration, there were significant increases in the Q-T interval, right atrial and right ventricular effective refractory periods, and right atrial and right ventricular monophasic action potential durations at 90% repolarization. Prolongation of the monophasic action potential duration was dependent on plasma sotalol concentration. There were no significant changes in these variables after propranolol. Sotalol, but not propranolol, acutely prolonged repolarization of human myocardium at a therapeutic plasma concentration. This property is unique among known competitive beta-adrenergic receptor antagonists.

1087 Use of Procainamide in Patients With the Wolff-Parkinson-White Syndrome to Disclose a Short Refractory Period of the Accessory Pathway

HEIN J. J. WELLENS, SIMON BRAAT, PEDRO BRUGADA, ANTON P. M. GORGELS, and FRITS W. BÄR

Procainamide administered intravenously (10 mg/kg body weight over 5 minutes) can be used to identify patients with the Wolff-Parkinson-White syndrome with a short anterograde refractory period of the accessory pathway. The development of complete anterograde block in the accessory pathway indicates that the patient has a re-

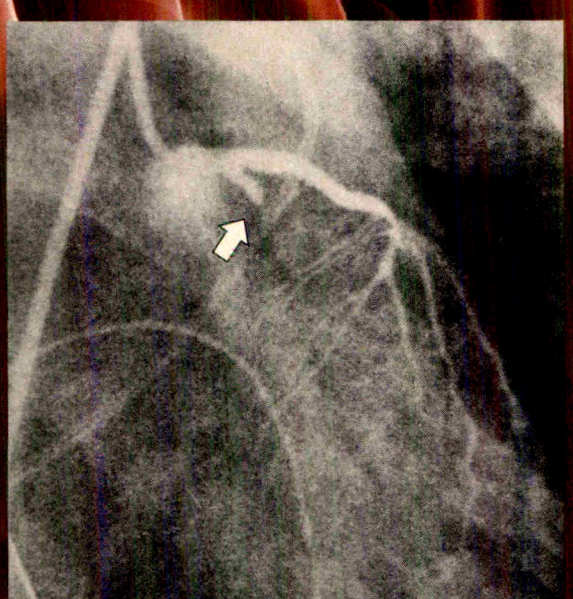
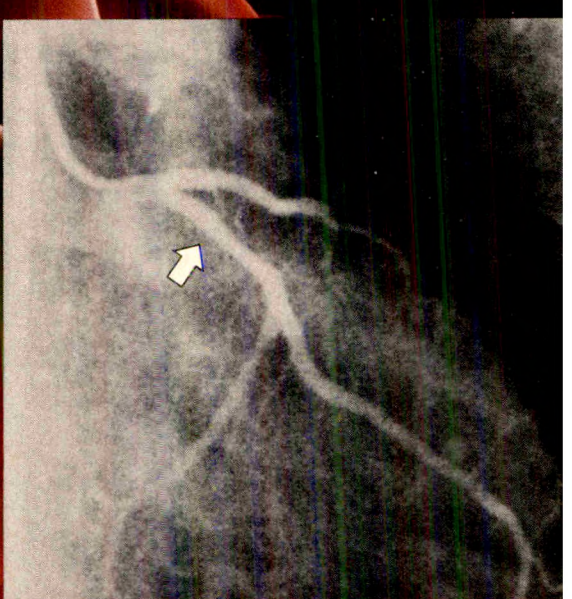
In evolving transmural myocardial infarction

New therapy quickly dissolves acute coronary artery thrombi





Pre-streptokinase
A 38-year-old woman in cardiogenic shock with acute lateral wall myocardial infarction caused by complete left

Post-streptokinase
The left circumflex is now widely patent beyond previous site of obstruction (arrow).

Please see full prescribing information, a summary

STREPTASE®
(streptokinase)

now indicated for acute coronary artery thrombosis.

Streptase® is infused directly into the involved artery during cardiac catheterization.

Efficacy demonstrated in multicenter studies

Coronary artery reperfusion was accomplished in 174 of 221 patients (79%) during evolving transmural myocardial infarction.

Randomized, controlled studies are in progress to determine the effects of reperfusion on salvage of myocardial tissue and reduction of mortality.

Side effects: few and readily controlled

There were no reports of allergic reaction or fever. Seven cases of bleeding at the puncture site and one case of moderate peritoneal bleeding were controlled without terminating therapy. Severe bleeding was reported in only one patient. This patient had a gastric ulcer six months prior to treatment.

Prompt initiation of treatment critical

The greatest benefit is achieved when therapy is initiated within six hours after the onset of symptoms.

Thrombolytic activity and safety record well documented

Streptase® has been effectively used worldwide for nearly a decade. Its record of clinical success is well matched by its record of safety, and both have been extensively reported in the medical literature.

STREPTASE®
(streptokinase)

A major advance in M.I. therapy

Please see full prescribing information, a summary of which appears on the following page.

STREPTASE® (streptokinase)
Brief Summary
CONSULT PACKAGE INSERT FOR FULL PRESCRIBING INFORMATION.

INDICATIONS AND USAGE

CORONARY ARTERY THROMBOSIS

Streptase® (streptokinase) has been reported to lyse acute thrombi obstructing coronary arteries, associated with evolving transmural myocardial infarction. Diagnosis of acute myocardial infarction has been confirmed, and the site of coronary thrombosis identified by selective coronary angiography. Other studies have demonstrated that (a) a thrombus is present in approximately 90% of patients evaluated within four hours of onset of symptoms; (b) when compared to concurrent or historical controls, the majority of patients who received intracoronary streptokinase within 6 hours of onset of symptoms showed a more immediate recanalization (within a few minutes vs hours/days) of the involved vessel.

IT HAS NOT BEEN ESTABLISHED THAT INTRACORONARY ADMINISTRATION OF STREPTOKINASE DURING EVOLVING TRANSMURAL MYOCARDIAL INFARCTION RESULTS IN SALVAGE OF MYOCARDIAL TISSUE, NOR THAT IT REDUCES MORTALITY. CONTROLLED STUDIES ADDRESSING THESE PARAMETERS ARE IN PROGRESS AND UNTIL COMPLETED, THOSE PATIENTS WHO MIGHT BENEFIT FROM THIS THERAPY CANNOT BE DEFINED.

CONTRAINDICATIONS

Because thrombolytic therapy increases the risk of bleeding, Streptase® (streptokinase) is contraindicated in the following situations:

- active internal bleeding
- recent (within 2 months) cerebrovascular accident, intracranial or intraspinal surgery (see WARNINGS)
- intracranial neoplasm

WARNINGS

Bleeding

The aim of Streptase® (streptokinase) therapy is the production of sufficient amounts of plasmin for the lysis of intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example, at sites of needle punctures, are also lysed and bleeding from such sites may occur.

Intramuscular injections and nonessential handling of the patient must be avoided during treatment with Streptase® (streptokinase). Venipunctures should be performed carefully and as infrequently as possible.

Should an arterial puncture be necessary during intravenous therapy, upper extremity vessels are preferable. Pressure should be applied for at least 30 minutes, a pressure dressing applied and the puncture site checked frequently for evidence of bleeding.

When internal bleeding occurs, it may be more difficult to manage than that which occurs with conventional anticoagulant therapy.

In the following conditions the risks of therapy may be increased and should be weighed against the anticipated benefits.

- Recent (within 10 days) major surgery, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels
- Recent serious gastrointestinal bleeding (within 10 days)
- Recent trauma including cardiopulmonary resuscitation
- Severe, uncontrolled arterial hypertension
- High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation
- Subacute bacterial endocarditis
- Hemostatic defects including those secondary to severe hepatic or renal disease
- Pregnancy
- Cerebrovascular disease
- Diabetic hemorrhagic retinopathy
- Prior severe allergic reaction to streptokinase
- Septic thrombophlebitis or occluded AV cannula at seriously infected site
- Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Should serious spontaneous bleeding (not controllable by local pressure) occur, the infusion of Streptase® (streptokinase) should be terminated immediately and treatment instituted as described under ADVERSE REACTIONS.

Use of Anticoagulants

Concurrent use of anticoagulants with intravenous administration of Streptase® (streptokinase) is not recommended. However, concurrent use of heparin may be required during intracoronary administration of Streptase® (streptokinase). Clinical studies with concurrent use of heparin and lower Streptase® (streptokinase) dosages employed during intracoronary administration have demonstrated no tendency toward increased bleeding that would not be attributable to the procedure or Streptase® (streptokinase) alone. Nevertheless, careful monitoring for excessive bleeding is advised.

Arrhythmias

Rapid lysis of coronary thrombi has been reported occasionally to cause reperfusion atrial or ventricular dysrhythmias requiring immediate treatment. During studies, careful monitoring for arrhythmia was maintained during and immediately following intracoronary administration of Streptase® (streptokinase).

PRECAUTIONS

Use in Pregnancy and Children

Safety and effectiveness of Streptase® (streptokinase) therapy in children and during pregnancy have not been established. Therefore, treatment of such patients is not recommended.

Drug Interactions

The interaction of Streptase® (streptokinase) with other drugs has not been studied. Drugs that alter platelet function should not be used during therapy. Common examples are: aspirin, indomethacin, and phenylbutazone.

Patient Monitoring

Before commencing thrombolytic therapy, it is desirable to obtain a thrombin time (TT), activated partial thromboplastin time (APTT), prothrombin time (PT), hematocrit and platelet count to obtain hemostatic status of the patient.

Intracoronary Artery Infusion

During studies, laboratory monitoring of hemostatic parameters during intracoronary artery infusion showed minimal changes, if any. Heparin was continued during therapy or instituted following therapy and monitored accordingly.

ADVERSE REACTIONS

The following adverse reactions have been frequently associated with intravenous therapy but may also occur with intracoronary artery infusion:

Bleeding

Minor bleeding occurs often with thrombolytic therapy mainly at invaded or disturbed sites. When lytic therapy is continued while local measures are used to control minor bleeding, do **not** reduce the dose as this will increase lytic activity since more plasminogen will be available for conversion to plasmin. Severe internal bleeding involving gastrointestinal, genitourinary, retroperitoneal or intracerebral sites, may occur. Several fatalities due to cerebral and other serious internal hemorrhage have occurred during intravenous thrombolytic therapy.

Should uncontrollable bleeding occur, Streptase® (streptokinase) infusion should be discontinued and, if necessary, blood loss and reversal of the bleeding tendency can be effectively managed with whole blood (fresh blood preferable), packed red blood cells and cryoprecipitate or fresh frozen plasma. Although the use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for streptokinase has not been documented, it may be considered in an emergency situation.

Allergic Reactions

Reactions attributed to possible anaphylaxis have been observed rarely in patients treated with Streptase® (streptokinase) intravenously. These ranged in severity from minor breathing difficulty to bronchospasm, periorbital swelling or angioneurotic edema. Other milder allergic effects such as urticaria, itching, flushing, nausea, headache and musculoskeletal pain have also been observed.

Mild or moderate reactions may be managed with concomitant antihistamine and/or corticosteroid therapy. Severe allergic reactions require immediate discontinuation of Streptase® (streptokinase), with adrenergics, antihistamines, or corticosteroids administered intravenously as required.

Fever

Although Streptase® (streptokinase) is nonpyrogenic in standard animal tests, approximately one-third of patients treated with Streptase® (streptokinase) intravenously have shown increases in body temperature of ≥ 1.5°F. Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is recommended.

DOSAGE AND ADMINISTRATION

Lysis of Coronary Artery Thrombi

During clinical studies, Streptase® (streptokinase) was administered selectively into the thrombosed coronary artery via coronary catheter placed by the Judkins or Sones Technique. When administered within 6 hours of onset of symptoms of acute transmural myocardial infarction, at a bolus dose averaging 20,000 IU and a maintenance dose averaging 2,000 IU/min for 60 minutes, greater than 75% of occlusions were opened in less than 1 hour.

How Supplied

Streptase® (streptokinase) is supplied as a lyophilized white powder in 6.5 mL vials (in packages of 10) with color-coded labels corresponding to the amount of purified Streptase® (streptokinase) in each vial as follows:

green — 250,000 IU blue — 750,000 IU

Store unopened vials at controlled room temperature (15-30°C).

fractory period of the accessory pathway 270 ms or longer. If preexcitation persists the patient has a short anterograde refractory period of the accessory pathway. The use of procainamide administered intravenously is a reliable and rapid method for identifying patients with the Wolff-Parkinson-White syndrome possibly at risk for circulatory insufficiency or sudden death in case of atrial fibrillation.

1090 Electrophysiologic Effects of Flecainide Acetate in Patients With Sinus Nodal Dysfunction

HARALD VIK-MO, OLE-JØRGEN OHM, and PER LUND-JOHANSEN

Flecainide acetate is a new antiarrhythmic agent with class I properties and a long plasma half-life for oral and intravenous use. The electrophysiologic effects of 1.5 mg/kg administered intravenously were evaluated in 11 patients with sinus nodal dysfunction. Flecainide acetate increased the corrected sinus node recovery time by 97%, whereas sinus cycle length and sinoatrial conduction time were not significantly changed. Flecainide acetate markedly prolonged the atrial and ventricular conduction and refractoriness, and thus appears to be a potent antiarrhythmic agent. However, sinus nodal function is depressed by flecainide acetate and caution is advised in the use of flecainide acetate in patients with sinus nodal dysfunction.

1095 Epicardial Activation of the Human Ventricle: Effects of Left Ventricular Hypertrophy

ISAAC WEINER, BRUCE MINDICH, and ROBERTA PITCHON

Epicardial mapping was performed in 10 patients with left ventricular hypertrophy. Nine patients had a single epicardial breakthrough site on the anterior right ventricle; 1 patient had a right ventricular breakthrough and a single left ventricular breakthrough. Nine patients had latest epicardial breakthrough at the left ventricular base and 1 patient had latest activation at the right base. Compared with patients without hypertrophy, patients with left ventricular hypertrophy had fewer left ventricular breakthrough points and were more likely to have latest activation at the left ventricular base. Thus, left ventricular hypertrophy is associated with marked changes in the pattern of epicardial activation.

1099 Influence of the Autonomic Nervous System on the Q-T Interval in Man

KEVIN F. BROWNE, DOUGLAS P. ZIPES, JAMES J. HEGER, and ERIC N. PRYSTOWSKY

Drugs that affect the autonomic nervous system can influence the Q-T interval directly or by changing the rate. Bazett's formula to correct for rate may be misleading after certain drug interventions. We tested this hypothesis in 20 patients receiving both propranolol and atropine. Sinus cycle length, measured Q-T interval (QT_m), atrially paced Q-T interval (QT_p), and the ventricular effective refractory period shortened after atropine plus propranolol ($p < 0.001$), but the corrected Q-T interval (QT_c) using Bazett's formula did not change. The sinus cycle length increased after propranolol but no change occurred in $Q\text{-}T_m$ or QT_p, although $Q\text{-}T_c$ markedly shortened ($p < 0.001$). Sinus cycle length, $Q\text{-}T_m$, and $Q\text{-}T_p$ decreased after atropine ($p < 0.01$) but $Q\text{-}T_c$ lengthened ($p < 0.01$). In summary, atropine and atropine plus propranolol shorten the Q-T interval independent of rate, demonstrating a direct vagal effect on the Q-T interval. Bazett's formula inaccurately predicts the Q-T interval after administration of atropine, propranolol, and atropine plus propranolol.

1104 Subcostal M-Mode Echocardiography of the Right Atrial Wall in the Diagnosis of Cardiac Arrhythmias

NIKSA DRINKOVIC

M-mode echocardiography of the right atrial (RA) wall can be easily recorded from the subcostal location. In a normal RA wall motion pattern, atrial contraction is represented by a markedly prominent posterior motion. The presence or absence of atrial contractions in the subcostal RA wall echocardiogram, their amplitude, and their timing may help in the diagnosis of cardiac arrhythmias with the simultaneously recorded electrocardiogram. Flat and hidden P waves can be accurately identified. It is possible to distinguish between atrial, ventricular, and nodal premature beats and to recognize atrial fibrillation, atrial flutter, paroxysmal atrial tachycardia, paroxysmal atrial tachycardia with block, atrioventricular (AV) nodal tachycardia, and supraventricular tachycardia with aberrant conduction. The diagnosis of wandering pacemaker, AV dissociation, sinoatrial block, and AV block is facilitated. On the basis of a study of 60 patients with various rhythm disturbances, it was concluded that analysis of the subcostal RA wall echocardiogram is a new, helpful noninvasive approach in the diagnosis of cardiac arrhythmias.

COMMENTS AND RECOMMENDATIONS:

Values normal
Basilar ventricular wall motion, Hyperkynesis at base of septum
Hypokynesis of posterior and lateral walls
Apex exam - Dyskynesis of the distal septum and akynesis of the lateral walls

Final Impression: Marked wall motion abnormalities; the only area appearing to move well being the Basilar anterior and septal wall.

From What Views and Where Should Measurements be Made

Mitral valve orifice size is assessed in the parasternal short axis view. Although 2DE provides multiple views for the measurement of the other variables mentioned, the parasternal long axis view presents several advantages for quantitation. The first is a perspective which is similar to that seen in M-Mode, with the distinct advantage of reliance primarily on axial resolution of the ultrasonic beam. Visualization of structures perpendicular to the direction of the ultrasonic beam is clearly superior to the resolution of structures which are parallel to the beam. In the parasternal long axis view, the interventricular septum, posterior left ventricular wall, and anterior and posterior walls of the left atrium are essentially perpendicular to the ultrasonic beam.

End-diastole is generally defined by the peak of the R wave as noted on simultaneous ECG tracings. Images which do not include an ECG tracing can use the frame showing the largest size attained by the left ventricular cavity, generally occurring right after the mitral valve A wave. End-systole is more accurately defined by mechanical events, inasmuch as Q-T interval changes may result in inconsistent relationships between the T wave and mechanical systole. End-systole is found by noting the smallest left ventricular cavity size and should occur just prior to the opening of the mitral valve.

The American Society of Echocardiography recommends that M-Mode measurements be made by use of the leading edge method.[3] That is, measurements from one structure to another should be made from the leading edge of the last echo produced by the anterior structure to the leading edge of the first echo produced by the posterior structure. Though preliminary work regarding this aspect of 2DE quantitation has been done, confirmation of this method is still incomplete. Technically it is often difficult to measure from the leading edge of several structures, particularly the left ventricular side of the septum. While appreciating this, measurements should probably be made as close to the leading edge method as feasible. All measurements in this paper were made using the leading edge method (as perceived in real-time) whenever possible.

Measurements of the Left Ventricle

Diameter measurements of the left ventricular cavity are made from a point on the posterior wall endocardium, at the level at which the chordae tendineae attach to the papillary muscle, to a point on the left side of the interventricular septum, such that a line connecting the two points is perpendicular to the long axis of the left ventricle (see Figs. 1 and 2). This measurement is made in end-systole and end-diastole. From these measurements, fractional shortening is obtained by the formula: diastolic diameter minus systolic diameter divided by diastolic diameter $\left(\frac{LVd-LVs}{LVd}\right)$. Though probably useful in diseased states which affect global left ventricular function uniformly, it must be appreciated that this simple fractional shortening formula is markedly limited in any state which causes wall motion abnormalities which are localized. Fractional shortening in the patient who has abnormalities of the interventricular septum or posterior wall at the level at which measurements have been made may have falsely depressed values suggesting left ventricular function is poorer than it actually is. Conversely, wall motion abnormalities of the lateral wall and apex wall may not be reflected by fractional shortening.

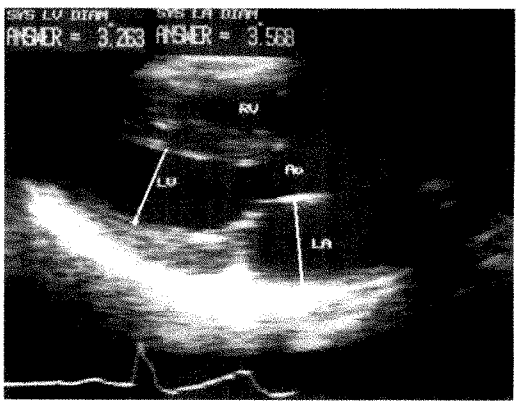

Fig. 1: Parasternal Long Axis Systole

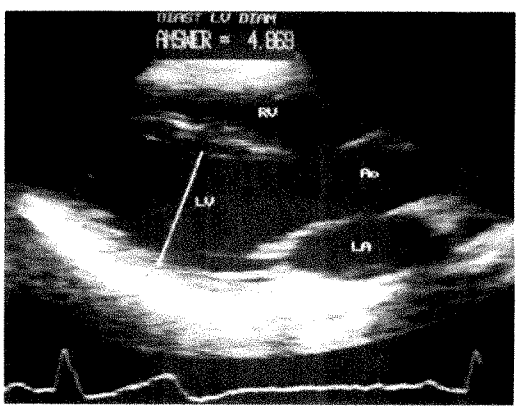

Fig. 2: Parasternal Long Axis Diastole

Several pitfalls in measuring dimensions of the left ventricular cavity should be noted. First and most importantly, measurements must be made from high quality echocardiograms; endocardial definition must be clear. Not infrequently, echos which provide valuable subjective information are simply inadequate for quantitation. Secondly, efforts must be made to insure that the measurement being made is a true maximal diameter of the left ventricle. Though theoretically more likely to provide this measurement than M-Mode echocardiography, 2DE too can provide misleading information if the parasternal long axis view is not taken through a true sagittal plane. Clues to suggest that the plane of the parasternal long axis is not proper include a distorted shape of the left ventricular cavity, marked variation in cavity size not related to contraction, and the appearance of a 'pseudo-apex'. Parasternal long axis views of the left ventricle which show an apparent apex are often out of the sagittal plane of the left ventricle such that this pseudo apex is probably formed by lateral or medial walls rather than the true LV apex. This results in a left ventricular diameter value which is smaller than that seen with a proper view.

Wall Thickness

Measurement of the thickness of the interventricular septum and posterior left ventricular wall are made in end-diastole. The level at which these measurements are made is dependent upon adequate visualization of endocardium and epicardium. Measurements are generally made between the papillary muscle and the mitral valve on the posterior left ventricular wall (see Fig. 3). Caution must be made to identify the papillary muscle so that this will not be included in assessment of wall thickness.

Methods for Clinical Measurements and Quantification of Two-Dimensional Echocardiography

Summary

The purpose of this protocol is to acquaint the reader with rationale and methods for quantitation of two dimensional echocardiographic images. Reasons for the theoretical advantages of these methods over M-Mode are given. Specific techniques for measurements of various parameters are described in detail and their utility is discussed. Finally, newer preliminary work in quantitative two dimensional echocardiography is described with reflection on its potential uses.

Quantitative Two Dimensional Echocardiography: An Overview

Why Quantitative Two Dimensional Echocardiography

Echocardiography (echo) has provided an invaluable tool in the non-invasive assessment of patients with cardiac disease. Qualitative assessment of echo patterns provide diagnoses in a large number of clinical entities. M-Mode echo has demonstrated particular usefulness when used quantitatively. Over the years, relatively simple M-Mode echo measurements have tremendously benefited the clinician by offering objective data for comparison with established values and for sequential comparison in the individual patient.

Though still in its infancy, quantitative two dimensional echocardiography (2DE) offers a number of potential benefits over M-Mode. Limited echo windows often provide M-Mode views which do not truly define the plane of interest. Variations in echocardiographic windows, chest configuration, heart shape, and heart size from patient to patient can result in markedly different planes of the left ventricle being defined as the maximum diameter by M-Mode. The problem of locating the true left ventricular diameter perpendicular to its long axis is partially solved by the improved visual presentation of 2DE. Similar problems involving the proper location of other M-Mode measurements are also partially solved by the use of 2DE.

Methods of Measurement

Just as the development of hard-copy M-Mode presented an opportunity for convenient quantitation of images, recent advances have made quantitative 2DE more attractive. Preliminary measurements of 2DE examinations had to be made directly from the viewing screen using calipers and grid markings or by a similar technique using Polaroid photographs. Recently, improved video tape recorders have made possible sharper images which are more suitable for measurements.

The Micro Sonics Image Analysis Computer is used to review patient studies archived on video tape as well as to make measurements. Segments of the video taped patient study are transferred to Video Disk allowing single frame or cine viewing in forward or reverse directions. Measurements are then made directly on the video screen with on-screen joy-stick controlled electronic calipers. Those measurements can then be combined in a variety of pre-entered formulas. A digitizing tablet could also be used to enter data from hard-copy.

Clinically Useful Two Dimensional Echocardiographic Measurements

Whose Echocardiogram Needs Measurement

All patients do not require extensive quantitation of their echocardiogram. Patients in whom measurements are particularly useful fall into two general categories. The first category is the patient whose quantitative values add to the overall assessment of the echocardiogram. This group includes those in which subjective assessment suggests that measurements might be abnormal, for instance, left ventricular hypertrophy or dilation of the left ventricle or atrium. The second category includes patients whose measurements might initially be normal, but for whom sequential studies are anticipated.

What Structures Should be Measured

Until well established criteria for 2DE measurements become widely accepted, it is probably prudent to rely primarily on measurements which are an extension of recognized M-Mode techniques. Preliminary data suggests that values from 2D images for diastolic and systolic left ventricular diameter, systolic left atrial diameter, fractional shortening of the left ventricle, and left ventricular posterior and septal wall thicknesses are similar to those seen with M-Mode. In addition, published data documents the usefulness of 2DE measurement of mitral valve area in patients with rheumatic mitral stenosis.[1,2]

Methods for Clinical Measurements and Quantification of Two-Dimensional Echocardiography

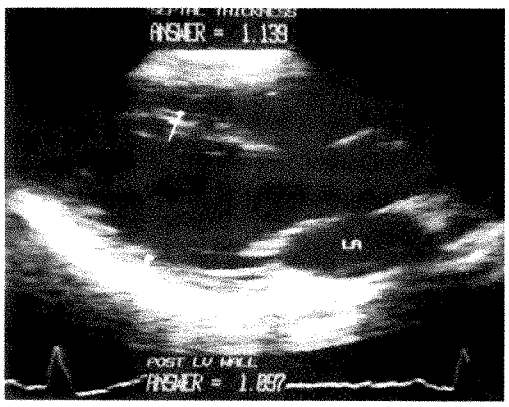

Fig. 3: Parasternal Long Axis Diastole

The Left Atrium

Assessment of the left atrial diameter is done in end-systole. This relatively simple measurement is made from a point on the posterior aortic root to the posterior wall of the left atrium (see Fig. 1). 'Side lobe' artifacts, which can be troublesome in M-Mode echo when making this measurement, are generally more easily identified with 2DE. Occasionally, the descending aorta or a large coronary sinus can be visualized posterior to the left atrial wall; these structures must be distinguished in relation to the atrium.

Rheumatic Mitral Stenosis

Planimetry of the mitral valve orifice in patients with rheumatic mitral stenosis is accomplished by use of the parasternal short axis view (Fig. 4). Care must be taken to assess the mitral valve at the level

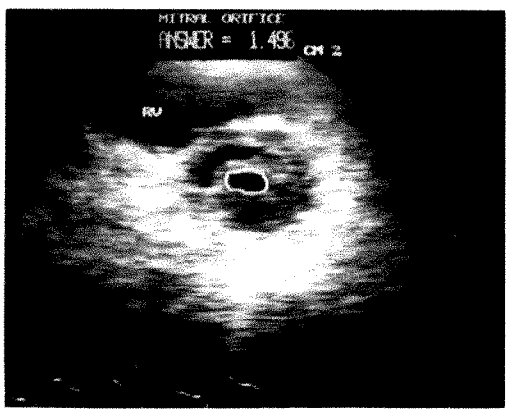

Fig. 4: Parasternal Short Axis Systole at Tips of Mitral Leaflets

of its leaflet tips. This is accomplished by obtaining recordings which slowly scan the body of the mitral valve apically toward the chordae tendineae. By use of this technique, both the technician and the person interpreting the echocardiogram can be relatively certain that the area being analyzed is in fact representative of the mitral valve orifice at its tips. Failure to insure that the area being planimetered is proper will result in computations which are falsely high, representing a measurement of the body of the mitral valve and not its true orifice. After locating the proper level, the image is slowly played until it demonstrates the largest mitral valve orifice size seen in early diastole. This area is then planimetered by utilizing computer assisted area assessment.

Other Chambers

Although most clinical echocardiographic laboratories make use of M-Mode quantitation of the right ventricular dimension, visualization with 2DE presents an image which is more confusing to measure than the left ventricle or left atrium. The unusual shape of the right ventricle as appreciated by 2DE, presents questions as to where measurements should be made. Assessment of this chamber and of the right atrium by 2DE will likely be a valuable contribution of the technique; however, this awaits further study.

Potentially Useful Two Dimensional Echocardiographic Measurements not Appreciated in M-Mode

Preliminary information both published and unpublished has suggested a great potential for measurements which are not possible using the M-Mode technique alone. In addition to linear measurements, area measurements of the left ventricle particularly in the parasternal short axis view, can easily be made with the Micro Sonics computer. By measuring this area at a particular level, for instance at the papillary muscles (see Figs. 5, 6), and by use of a similar formula as used for fractional shortening, fractional area change can be calculated (Fig. 7): Diastolic Area minus Systolic Area divided by Diastolic Area ($\frac{DA-SA}{DA}$). This value may theoretically provide more information regarding ventricular function than single plane fractional shortening.

Volumetric data from the left ventricle and other chambers has been obtained using a wide variety of geometric assumptions.[4] Planimetry of the area of the left ventricle in apical views has been used to calculate volumes in much the same way as is done using right anterior oblique angiograms.[5] Kennedy and Dodge formulas, as well as modified Simpson's Rule formulas, can be utilized with this

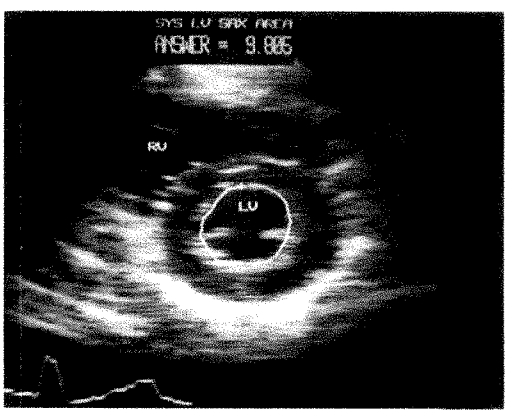

Fig. 5: Parasternal Short Axis Systole Papillary Level

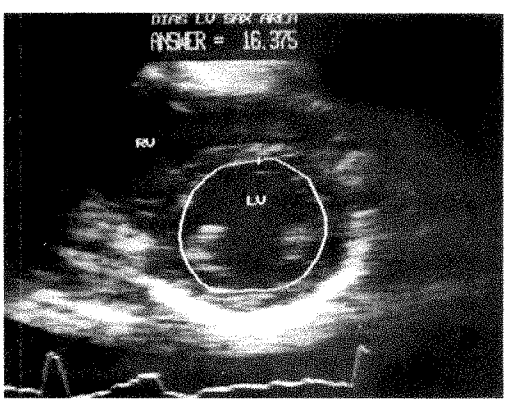

Fig. 6: Parasternal Short Axis Diastole Papillary Level

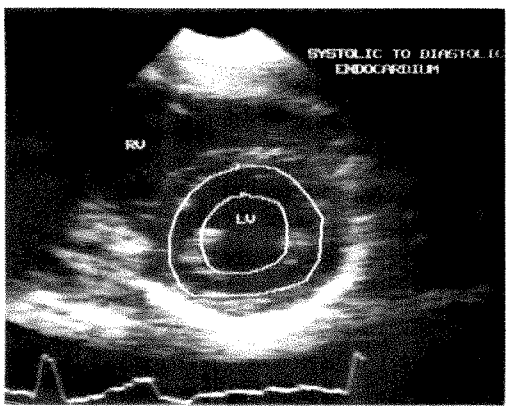

Fig. 7: Parasternal Short Axis Comparison Systole and Diastole.

technique. More complex Simpson's Rule formulas employ multiple views of the left ventricle and usually require computer assistance.[6,7] One rather simple geometric assumption which has shown fair correlation in some studies is the "Bullet" or cylinder-ellipse model where volume is equal to 5/6 times short axis area times the length of the left ventricle (LVVolume = 5/6AL).[4,8] This calculation can be made from the short axis measurement described previously and a left ventricular length measurement made from an apical view.

Assessment of ejection fraction has been made by some investigators by use of volumetric data obtained by the various geometric assumptions. More recently, at least one technique has been proposed which provides a calculation of ejection fraction by assessment of diastolic and systolic diameters in multiple views at various levels.[9]

Conclusion

Quantitative echocardiography provides relatively inexpensive non-invasive data for comparison with established values and for comparison with previous examinations on the same patient. Two dimensional echocardiography has several theoretical advantages over M-Mode for quantitation. Until more extensive 2DE quantitative information is available, measurements which are an extension of the M-Mode technique can reliably be used. Preliminary reports suggest that volumetric and ejection fraction data can be obtained utilizing two dimensional echocardiography; these techniques may come into general clinical use in the near future.

METHODS

1109 Application of Body Surface Mapping to Exercise Testing: S-T_{80} Isoarea Maps in Patients With Coronary Artery Disease

FRANK G. YANOWITZ, G. MICHAEL VINCENT, ROBERT L. LUX, MAHESH MERCHANT, LARRY S. GREEN, and J. A. ABILDSKOV

Body surface electrocardiographic maps were obtained during exercise testing in 25 men with coronary artery disease. Torso potential distributions at 192 locations were derived from a 32 lead electrode array. The S-T segment was characterized by the spatial distribution of an 80 ms S-T segment integral. Body surface regions where the S-T_{80} areas were −8 mv·ms or greater were identified in 18 of 25 patients. The most negative site on the isoarea maps was called the "S-T_{80} minimum." The S-T_{80} minima were located 1 or 2 electrode rows away from the standard V_4–V_6 electrode positions in 6 of 18 patients. The data suggest that the standard electrocardiographic leads may not be optimal for identifying S-T segment depression in all patients with coronary disease. Furthermore, body surface mapping during exercise provides a more quantitative and qualitative method for examining the ischemic response to exercise.

1114 Scintigraphic Prediction of Pulmonary Arterial Systolic Pressure by Regional Right Ventricular Ejection Fraction During the Second Half of Systole

BRUCE J. FRIEDMAN and B. LEONARD HOLMAN

In 49 patients who had undergone gated equilibrium ventriculography and cardiac catheterization within a several-day interval, total and fractional portions of global and regional right ventricular ejection fraction were correlated with pulmonary arterial systolic pressure. The fractional ejection of blood from the region of the right ventricular free wall during the second half of systole as measured by gated equilibrium scintigraphy accurately detected pulmonary hypertension. Although a good correlation between pulmonary arterial systolic pressure and regional right ventricular ejection during the second half of systole was found, small changes in ejection fraction reflect large changes in pressure in the abnormal range, limiting the technique's application as a quantitative index of pulmonary arterial pressure.

1120 Effect of Beam Directional Alterations on Left Ventricular Shortening Fraction

HEINZ R. HOENECKE, Jr., STANLEY J. GOLDBERG, DAVID J. SAHN, HUGH D. ALLEN, and LILLIAM M. VALDES-CRUZ

The effect of ultrasonic beam direction on echocardiographically determined shortening fraction of the left ventricle was examined. This was accomplished by studying results of several M-mode lines at the chordal level from a single 2-dimensional image. The results demonstrate that many M-mode lines that deviate from the meridian of the ventricle may provide acceptable M-mode tracings but considerably different results for shortening fraction. Accordingly, if shortening fraction is to be used clinically, spatial orientation is recommended.

1124 Low Energy Countershock Using an Intravascular Catheter in an Acute Cardiac Care Setting

RAYMOND YEE, DOUGLAS P. ZIPES, SAJAD GULAMHUSEIN, MICHAEL J. KALLOK, and GEORGE J. KLEIN

A tripolar countershock catheter was inserted into 8 patients for purposes of cardioversion and defibrillation of refractory ventricular tachyarrhythmias. The catheter was inserted percutaneously through the left subclavian vein with the distal tip in the right ventricular apex, and direct current countershock was delivered using a standard commercially available defibrillation unit. No complications or lead dislodgment occurred after a total of 45 patient-days with the catheter in situ. Six patients required catheter countershock for 91 episodes of ventricular tachycardia, 3 of ventricular flutter, and 6 of ventricular fibrillation. Catheter countershock was delivered 115 times and was successful on 93 occasions (80%), using energy doses of 2.5 to 40 J. Burst pacing to terminate ventricular tachycardia was performed successfully 10 times in 1 patient. Thus, catheter countershock can be safely and effectively administered in an acute care setting and is an alternative to repeated transthoracic countershock for termination of unstable refractory ventricular tachyarrhythmias.

1130 Intraoperative 2-Dimensional Echocardiography: Ejection of Microbubbles From the Left Ventricle After Cardiac Surgery

PAUL C. RODIGAS, FRANCES J. MEYER, GEORGE B. HAASLER, JEROME M. DUBROFF, and HENRY M. SPOTNITZ

The prevalence of ejection of microbubbles from the left ventricle after open-heart surgery was studied with intraoperative 2-dimensional echocardiography using a gas-sterilized transducer. High-quality images of the left atrium, left ventricle, and ascending aorta were obtained and demonstrated microbubbles as bright echo reflec-

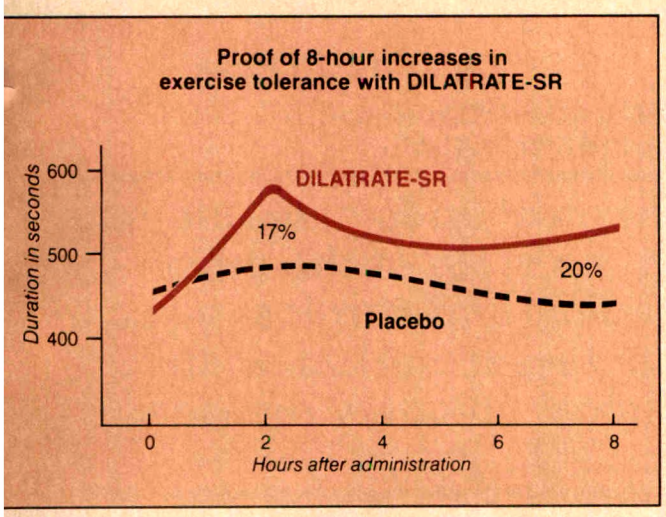
ONLY
DILATRATE®-SR
(isosorbide dinitrate)
HAS CLINICAL

n treadmill tests, DILATRATE-SR produced a 17% ncrease in mean total exercise duration within 2 hours; fter 8 hours the increase was 20%.



*Exercise duration and work capacity increased for a full 8 hours in angina patients**

In a double-blind, placebo-controlled study involving patien with chronic stable angina, significant improvement in exer cise capacity was sustained for eight hours following admi istration of one 40 mg DILATRATE-SR capsule.[1]

This is the first study to demonstrate that a sustained-release nitrate formula can provide clinical effectiveness fo a full eight hours. And, the advantage over placebo did not appear to be decreasing at the end of eight hours.

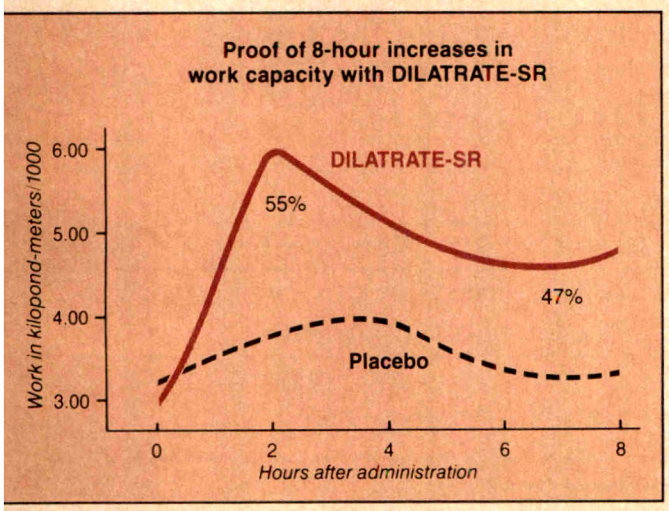
Increases in exercise tolerance translate into true patient benefits

Exercise tolerance tests provide objective measurements o improvement in work capacity that can be correlated with t anginal patient's daily activities. These results demonstrate that DILATRATE-SR can provide a positive impact on your patient's lifestyle.

Clinical support of plasma level studies

This clinical study supports previous blood assays which demonstrated that DILATRATE-SR provides significant plasma levels of ISDN for up to 12 hours.[2]

PROOF: 8-hour antianginal activity*



A 20% increase in duration of treadmill exercise means another minute or two at higher speed on a steeper ncline. When mean work performance was calculated, DILATRATE-SR provided a 47% increase at 8 hours.

A unique method of delivering isosorbide dinitrate

DILATRATE-SR employs a unique delivery system — an advanced microdialyzing membrane that releases ISDN at a steady rate independent of gastric pH and enzymes. The water-activated membrane continually adjusts permeability to maintain constant nitrate release.

DILATRATE-SR simplifies antianginal therapy

The proven sustained activity of DILATRATE-SR offers anginal patients convenient b.i.d. dosage and can reduce the need for sublingual nitroglycerin.

BRIEF SUMMARY

Indications: Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: When taken by the oral route, is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATION: Idiosyncrasy to this drug.

WARNINGS: Data supporting the use of nitrates and nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

PRECAUTIONS: Tolerance to this drug, and cross-tolerance to other nitrates or nitrites may occur.

In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome it is suggested that either the 5 mg. or 10 mg. oral tablets or 2.5 mg. or 5 mg. sublingual tablets be the preferred therapy.

ADVERSE REACTIONS: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

For full prescribing information, consult package insert.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

tions moving from the left atrium to the aorta. The overall incidence of this phenomenon was 49% in 79 patients, and the frequency and extent of microbubble formation was related to the need for cardiotomy, providing an easy source of entry for air. No patient studied manifested evidence of a cerebrovascular accident. It is concluded that 2-dimensional echocardiography is useful in detecting intracardiac microbubbles and therefore may be instrumental in their elimination.

EXPERIMENTAL STUDIES

1133 Impaired Collateral Blood Flow Reserve Early After Nontransmural Myocardial Infarction in Conscious Dogs

RANDOLPH E. PATTERSON, BEVERLY A. JONES-COLLINS, and ROGER AAMODT

The purpose of this study was to determine the adequacy of collateral blood flow reserve of myocardium surviving a nontransmural myocardial infarction. Ventricular pacing increased the heart rate from 110 to 220 beats/min without changing aortic or left atrial pressure 3 to 4 days after occlusion of 2 major coronary arteries in conscious dogs. Subendocardial and mid-myocardial ischemic zone samples contained infarcted tissue and had low control values of coronary vascular conductance (flow/100 mm Hg mean aortic pressure), which tended to decrease during pacing. Coronary vascular conductance in normal zone myocardium increased 35% from control to pacing but did not change in surviving tissue located in the subepicardial layers of collateral-dependent myocardium. Thus, collateral vessels increase blood flow to nearly normal levels by 3 to 4 days after myocardial infarction, but lack reserve capacity to increase blood flow in response to stress.

1141 Relation Between Regional Distribution of Thallium-201 and Myocardial Blood Flow in Normal, Acutely Ischemic, and Infarcted Myocardium

ALAN CHU, ROBERT H. MURDOCK, Jr., and FREDERICK R. COBB

This study compares myocardial localization of thallium-201 with direct measurements of myocardial perfusion in normal, acutely ischemic and recently infarcted myocardium. Studies were performed in 6 chronically instrumented animals subjected to myocardial infarction by occlusion of the proximal left circumflex coronary artery. Four days after myocardial infarction, thallium-201 and 9 $\pm$ 1 μm microspheres were injected simultaneously after acute left anterior descending coronary artery occlusion; the animals were killed 5 minutes later and the entire left ventricle was sectioned into 1 to 2 g samples. Regression analyses between thallium-201 activity and regional myocardial blood flow using all myocardial samples demonstrate a very close linear relation in each dog; r values were 0.98 or greater, indicating that the initial localization of thallium-201 in acutely ischemic and recently infarcted myocardium as a function of regional blood flow was essentially identical.

HISTORICAL STUDIES

1145 Jacob Mendez DaCosta: Medical Teacher, Clinician, and Clinical Investigator

CHARLES F. WOOLEY

J. M. DaCosta was recognized during his lifetime as an authority on physical diagnosis and had an unexcelled reputation as a clinical teacher. Chairman of Medicine at the Jefferson Medical College for 19 years, president of the College of Physicians of Philadelphia in 1884 and again in 1895, he was one of the original members of the Association of American Physicians and its president in 1897. Earlier in his career, his extensive Civil War study of "a form of cardiac malady common among soldiers . . . the study of which is equally interesting to the civil practitioner" was described in his 1871 report "On Irritable Heart; A Clinical Study of a Form of Functional Cardiac Disorder and Its Consequences." Soon labeled *DaCosta's syndrome*, the irritable heart lineage can be traced through the *soldier's heart*, the *effort syndrome*, and *neurocirculatory asthenia* in World War I, *anxiety neurosis* in World War II, and the *mitral valve prolapse syndrome* in the second half of the 20th century.

Visit us at The AHA. And see why we're called Pacesetter.

During the American Heart Association Sessions, we'll both have a special opportunity. You, to participate in our stimulating scientific forums and breakfast discussions. Us, to show off our latest technological innovations.

We've set the pace for our industry for years, and we're at it again. A partial preview:

Innovation:

- Programalith® III, our smallest multiprogrammable, single- and dual-chamber pacemaker with expanded telemetry.
- AFP,™ with multiprogrammable DDD pacing and with telemetry of stored, measured and physiologic wave form data.
- The new Model 388 Telemetry System, providing multiprogrammability and expanded telemetry for all Programalith series pacers.
- New *"Fast Pass"*™ unipolar and bipolar silicone rubber leads with a special coating, smaller diameters and excellent handling characteristics.

Scientific Forums:

An all-new exhibit with a special built-in theatre, where we'll be covering:

- Intracardiac Event Recording;
- Pharmaceutical Infusion Systems;
- Pacing Systems with Surface and Endocardial EKG Telemetry Capabilities;
- Clinical Experience with DDD Pacing;
- And more!

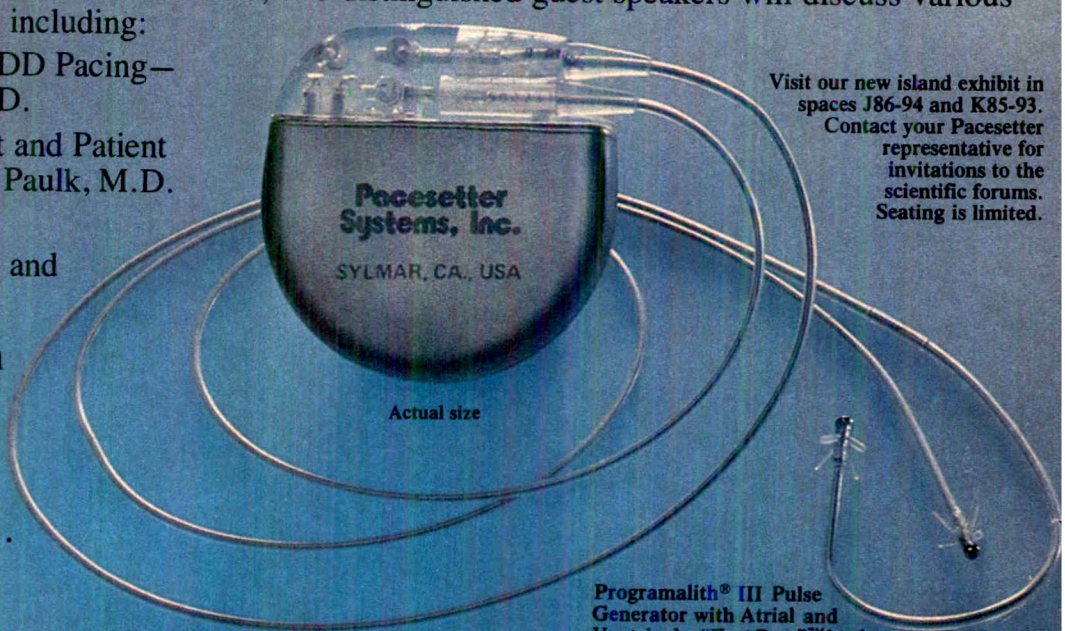
Breakfast Discussions:

Monday and Tuesday, November 15 and 16, two distinguished guest speakers will discuss various aspects of DDD pacing, including:

- Hemodynamics of DDD Pacing—Charles L. Byrd, M.D.
- Clinical Management and Patient Follow-up – E. Alan Paulk, M.D.

Contact your Pacesetter representative for details and invitations.

Plan on visiting with us. You'll see why our whole industry now knows who the real Pace*setter* is.



Actual size

Visit our new island exhibit in spaces J86-94 and K85-93. Contact your Pacesetter representative for invitations to the scientific forums. Seating is limited.

SYMPOSIUM ON VERAPAMIL THERAPY FOR ANGINA PECTORIS. PART III: STUDIES IN EFFORT-RELATED ANGINA

MILTON PACKER, Guest Editor, and WILLIAM H. FRISHMAN, Guest Co-Editor

1153 Verapamil Therapy for Stable Exertional Angina Pectoris

DONALD A. WEINER and MICHAEL D. KLEIN

The clinical and exercise response to therapy with the calcium-channel blocking agent verapamil was assessed in 26 patients with stable exertional angina pectoris using a double-blind placebo-controlled randomized crossover study design. Verapamil (480 mg daily) reduced the frequency of anginal attacks and the number of nitroglycerin tablets consumed and increased exercise duration compared with placebo. Adverse effects from verapamil were few and consisted primarily of constipation in 6 patients. A total of 193 patients have been entered in 6 independent clinical trials, which have compared verapamil with placebo for the treatment of stable exertional angina pectoris, using a similar study design. The combined evidence from all of these studies indicates that verapamil is a highly effective and safe drug for the treatment of stable effort-related angina pectoris.

1158 Calcium Channel Blockade as Primary Therapy for Stable Angina Pectoris. A Double-Blind Placebo-Controlled Comparison of Verapamil and Propranolol

V. BALA SUBRAMANIAN, MICHAEL J. BOWLES, ANTHONY B. DAVIES, and EDWARD B. RAFTERY

The effectiveness and safety of the beta-adrenergic blocking agent propranolol and the calcium channel antagonist verapamil were studied using a placebo-controlled, double-blind, randomized crossover protocol in 22 patients with chronic stable angina pectoris. Both verapamil and propranolol increased exercise tolerance, but the increase with verapamil was significantly greater. Both drugs prolonged the exercise duration to 1 mm of S-T depression to a similar degree; both drugs decreased the resting heart rate, but the rate decreased more with propranolol than with verapamil. Neither drug produced significant adverse reactions. This study, along with 8 similar double-blind placebo-controlled randomized investigations comparing verapamil with propranolol, indicate that verapamil is as effective and safe as propranolol in relieving symptoms and improving exercise tolerance in patients with chronic stable angina pectoris.

1164 Comparison of Oral Propranolol and Verapamil for Combined Systemic Hypertension and Angina Pectoris. A Placebo-Controlled Double-Blind Randomized Crossover Trial

WILLIAM H. FRISHMAN, NEAL A. KLEIN, PHILIP KLEIN, JOEL A. STROM, ROBERT TAWIL, ROGER STRAIR, BOWEN WONG, STEVEN ROTH, THIERRY H. LeJEMTEL, SIMCHA POLLACK, and EDMUND H. SONNENBLICK

The relative effectiveness of verapamil and propranolol were compared in 12 patients with both stable angina pectoris and mild to moderate systemic hypertension, using a placebo-controlled, double-blind, randomized crossover protocol. Both propranolol and verapamil produced a similar decrease in the frequency of anginal attacks and a similar increase in exercise duration. Both drugs reduced supine and standing systolic and diastolic blood pressure measured at rest; however, verapamil had greater effects on standing diastolic blood pressure than propranolol. Plasma renin activity was increased by verapamil but was reduced by propranolol; neither drug altered plasma aldosterone levels. Verapamil appears to be a safe and effective alternative to propranolol for improving exercise tolerance and reducing elevated systemic blood pressure in patients with both angina pectoris and systemic hypertension.

1173 Rationale for the Choice of Calcium Antagonists in Chronic Stable Angina. An Objective Double-Blind Placebo-Controlled Comparison of Nifedipine and Verapamil

V. BALA SUBRAMANIAN, MICHAEL J. BOWLES, NARDEV S. KHURMI, ANTHONY B. DAVIES, and EDWARD B. RAFTERY

The effectiveness and safety of verapamil, nifedipine, and placebo in patients with chronic stable angina pectoris were compared in 2 clinical trials. In the first study, nifedipine (30 mg daily) did not differ from placebo in 24 patients with exertional anginal symptoms. In the second study, verapamil (360 mg daily), nifedipine (60 mg daily), and placebo were compared in 32 patients with chronic stable angina using a double-blind crossover study design. Compared with placebo, both nifedipine and verapamil prolonged exercise duration, but the im-

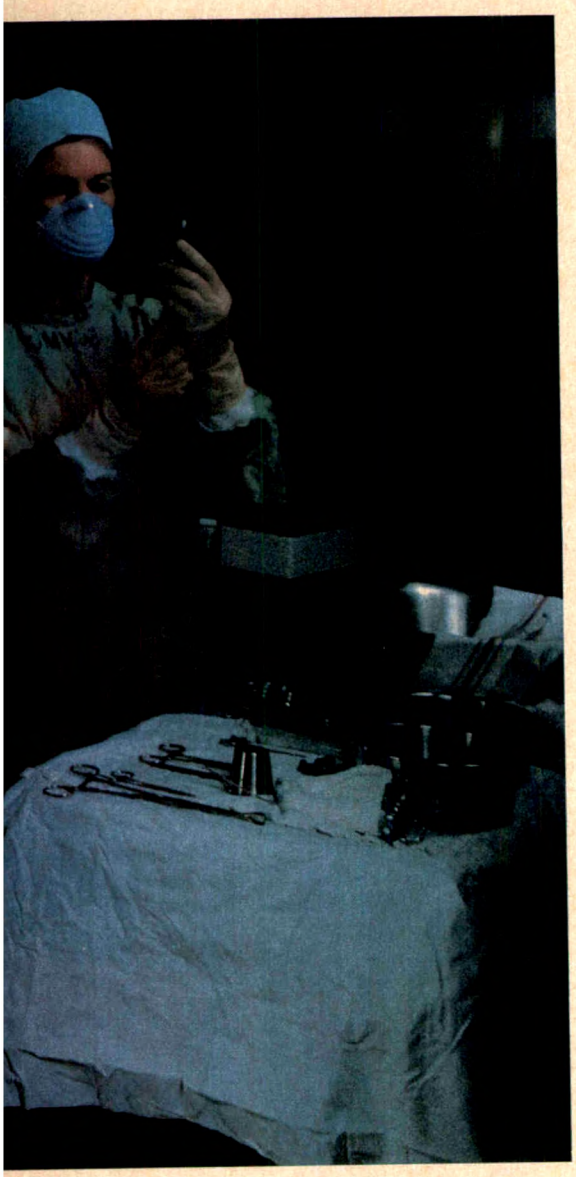
DIASONICS

TOTALLY DIGITAL CORONARY

Superior images with high frame

IT'S WHERE IMAGING IS GOING...

ARTERY IMAGING...AngioVue.™
rate processing and image enhancement.



Coronary artery imaging with a totally digital system.

Diasonics' new AngioVue Digital Angiography System produces digital images clinically equivalent to cine film through digital image manipulation and image enhancement algorithms. The AngioVue allows clear visualization of coronary arteries with fine detail. It's all possible through Diasonics' unique pulsed mode digital acquisition gated at 8/fps with 512x512 resolution—and totally digital storage.

Faster, more accurate, quantitative ventriculography.

By combining superior digital images acquired at 30 fps and powerful computer analysis, faster, more accurate ventriculography is performed.

Through standard area length techniques and densitometry, AngioVue provides easy calculation of ejection fraction, C.O. and C.I. Diasonics' advanced software allows segmental wall motion and functional image analyses. And, with its 256x256 matrix, ventriculography is performed with better resolution than nuclear cardiology.

Now, digital angiography for all cath lab imaging procedures.

With the Diasonics AngioVue, you can more effectively perform functional studies, PTCA, drug therapy and vascular imaging. You use less dye permitting more injections with less risk to the patient. And AngioVue interfaces directly with your existing equipment and can provide dual room and biplane capabilities.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE. In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA. Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS
—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).
—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).
—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).
—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).
The appearance of these tablets is a trademark of Ayerst Laboratories.
Store at room temperature (approximately 25° C).
INJECTABLE
—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).
Store at room temperature (approximately 25° C).

provement with verapamil was greater than with nifedipine. Seven patients had increasing angina while on nifedipine, but none did while on verapamil; this appeared related to the higher heart rates with nifedipine than with placebo. At the doses used, verapamil was more effective and was better tolerated than nifedipine in patients with chronic stable angina pectoris.

1180 Clinical Relevance of Verapamil Plasma Levels in Stable Angina Pectoris

WILLIAM FRISHMAN, EDWARD KIRSTEN, MICHAEL KLEIN, MICHAEL PINE, STACEY M. JOHNSON, L. DAVID HILLIS, MILTON PACKER, and ROBERT KATES

In 77 patients who received verapamil for treatment of angina pectoris, there was a sixfold interpatient variation in verapamil plasma concentrations, but plasma concentrations were linearly related to doses of the drug (240 to 480 mg/day) in the same patient. Although verapamil produced a significant improvement in exercise tolerance in most patients, the increase in exercise time was not related to plasma levels of the drug; an increase in the dose of verapamil for 320 to 480 mg daily produced a 71% increase in plasma levels of the drug but no significant increase in exercise tolerance. Despite the high plasma drug levels, the average increase in P-R interval with 480 mg of verapamil was only 8% (161 at 18 to 174 at 22 ms), and only 6 patients had first-degree heart block. Determination of plasma levels of verapamil are of limited value in the management of patients with angina pectoris.

1185 Long-Term Effectiveness of Verapamil in Stable and Unstable Angina Pectoris. One-Year Follow-Up of Patients Treated in Placebo-Controlled Double-Blind Randomized Clinical Trials

STEPHEN SCHEIDT, WILLIAM H. FRISHMAN, MILTON PACKER, JAWAHAR MEHTA, OBERDAN PARODI, and V. BALA SUBRAMANIAN

The clinical responses to 12 months' treatment with verapamil were evaluated in 63 patients with stable and unstable angina pectoris in whom the effectiveness of verapamil had been established in short-term double-blind placebo-controlled clinical trials. In 41 patients with effort-related angina, verapamil produced a sustained reduction in the frequency of anginal attacks and consumption of nitroglycerin for periods exceeding 1 year; this prolonged improvement was confirmed by serial treadmill exercise testing in 21 patients. In 22 patients with unstable angina at rest, verapamil produced a sustained amelioration of anginal symptoms. However, the incidence of death and myocardial infarction remained high and was similar to that previously reported in large clinical studies using either combinations of verapamil and nitrates, nifedipine and propranolol, or propranolol and nitrates.

1191 Comparative Effects of Abrupt Withdrawal of Propranolol and Verapamil in Angina Pectoris

WILLIAM H. FRISHMAN, NEAL KLEIN, JOEL STROM, MARTIN N. COHEN, HARRY SHAMOON, HOWARD WILLENS, PHILIP KLEIN, STEVEN ROTH, LOUIS IORIO, THIERRY LEJEMTEL, SIMCHA POLLACK, and EDMUND H. SONNENBLICK

The comparative effects of withdrawal from long-term administration of propranolol and verapamil were assessed in a placebo-controlled double-blind randomized crossover study of 20 patients with stable angina pectoris. All 20 patients were withdrawn from verapamil without evidence of a rebound increase in frequency of anginal attacks, blood pressure, heart rate, and rate-pressure product, and without a rebound deterioration in exercise tolerance. In contrast, with propranolol withdrawal, 2 patients (with the highest baseline rate of anginal attacks) had a severe exacerbation of the anginal syndrome and could not undergo exercise; the other 18 patients were withdrawn from propranolol without incident. Plasma catecholamine levels were increased with exercise compared with rest during all treatments; however, the catecholamine levels during exercise were significantly higher with propranolol than with verapamil and placebo.

COMP SCAN
HOLTER ANALYSIS...
RESULTS THAT SPEAK FOR THEMSELVES
compu-scan
Medical Systems

omp-scan uses modern computer technology to ccurately locate and classify each irregular heart-eat that occurs in a 24 hour Holter ECG procedure. omp-scan then compiles and presents that informa-on in a format that enables rapid verification and nterpretation of scanned results...so, the cardiologist an concentrate on patient diagnosis and treatment.

Comp-scan's rapidly avail-ble and precise reports are resented in the format needed y the technician and the ardiologist. Comprehensive ummaries list all major events vith ectopics classified by type nd by the hour of occurrence. Classified events can be quickly nd easily verified using the ninute by minute breakdown f any selected hour. Or, the ser can verify results by speci-ic arrhythmia type using Comp-scan's exclusive auto-nated arrhythmia search fea-ture. Summary reports are presented on the color screen for immediate review, with permanent records provided by the high speed printer. ECG complexes are presented on a separate large display screen with permanent printout available from the 2-channel chart recorder.

ACCURATE RESULTS

Comp-scan's computer has been programmed to recognize ectopic events. Once the operator has defined a patient's normal ECG, Comp-scan works by itself to locate and classify each ectopic event. Advanced hardware and software design allows Comp-scan to reject artifact while accommodating normal physiological changes.

CONSISTENT RESULTS

Comp-scan's computer never gets tired or looks away. Every heartbeat of every Holter tape is analyzed with precisely the same criteria. While the system is automatically scanning, the operator can perform other tasks. And when analysis is complete, the operator's expertise is focused on verification and interpretation of results.

VERIFIABLE RESULTS

Comp-scan can recall every heartbeat by the minute in which it occurred. So, each ectopic event that was detected by Comp-scan can be quickly displayed on the ECG screen for rapid verification. And those results can be edited and documented with patient ID for permanent record.

CLINICAL STUDIES

Intracoronary Thrombolysis in Acute Myocardial Infarction: Duration of Ischemia as a Major Determinant of Late Results After Recanalization

FRANZ SCHWARZ, MD, GERHARD SCHULER, MD, HUGO KATUS, MD, MANFRED HOFMANN, MD, JOACHIM MANTHEY, MD, HARALD TILLMANNS, MD, HELMUTH C. MEHMEL, MD, and WOLFGANG KÜBLER, MD

To define the effect of duration of myocardial ischemia on the late results after successful thrombolysis in patients with acute transmural myocardial infarction, data on 39 patients treated with intracoronary infusion of streptokinase were analyzed. Patients with successful recanalization of infarct vessel and a time lag between onset of symptoms and reperfusion less than 4 hours were assembled in group A1 (n = 15), and patients with successful recanalization but a time lag of more than 4 hours (n = 17) in group A2. Group B consisted of 7 patients with unsuccessful thrombolysis. Coronary anatomy, left ventricular volume, ejection fraction, and regional ejection fraction of infarct area were determined before and 4 weeks after thrombolysis with cineangiography. Serum creatine kinase activity was serially measured.

Before intervention, the groups were comparable with regard to age, Killip class, localization of infarction, incidence of previous infarction, Gensini score of coronary anatomy, left ventricular volume, ejection fraction, regional ejection fraction of infarct area, and serum creatine kinase activity. Four weeks after the intervention, patients in group A1 had a higher ejection fraction (59%) and regional ejection fraction of infarct area (39%) than patients in group A2 (ejection fraction: 49%, $p < 0.05$; regional ejection fraction: 26%, $p < 0.05$) and group B (ejection fraction: 44%, $p < 0.05$; regional ejection fraction: 25%, $p = 0.05$). Peak serum creatine kinase activity measured during the acute illness was lower in group A1 (764 U/liter) than in group A2 (1,580 U/liter, $p < 0.05$) and group B (2,106 U/liter, $p < 0.05$).

Thus, contraction of infarct area was improved and enzymatic estimate of infarct size was reduced after early as compared with late reperfusion in patients with acute myocardial infarction.

The beneficial effect of coronary arterial reperfusion in acute transmural myocardial infarction is critically dependent on the duration of coronary occlusion.[1-3] Nonsurgical reperfusion has been established by use of intracoronary thrombolysis by streptokinase infusion in patients with acute myocardial infarction.[4,5] Improvement of left ventricular function was documented after thrombolysis as measured with the ejection fraction.[6] The effect of the duration of myocardial ischemia on contraction of infarct area and enzymatic estimate of infarct size is not yet well defined. Therefore the aim of the present study was to assess the effects of early reperfusion (within 4 hours after onset of symptoms) and late reperfusion (more than 4 hours after onset of symptoms) on left ventricular function and enzymatic estimate of infarct size.

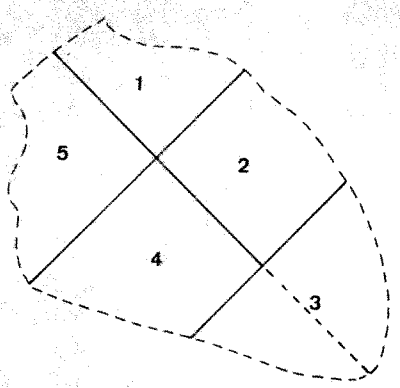

FIGURE 1. Right anterior oblique ventriculogram showing the 5 areas analyzed. Systolic contraction was measured as percent area reduction. For anterior infarction areas 1, 2, and 3 were averaged; for inferior infarction areas, 3, 4, and 5.

Methods

Patients: Thirty-nine patients with acute transmural myocardial infarction, in whom intracoronary infusion with streptokinase was performed in order to recanalize the obstructed coronary artery, were studied. These patients were selected from a consecutive series of 62 patients who underwent intracoronary thrombolysis because they had a second invasive study after 4 weeks. Five of the remaining 23 patients died during the acute phase of their disease and therefore could not be restudied, and 18 patients refused the second invasive study. The diagnosis of transmural myocardial infarction was based on (1) acute chest pain lasting for more than 30 minutes, (2) persistent S-T segment elevation (greater than 2 mm in at least 3 leads of the standard 12 lead electrocardiogram) lasting for more than 30 minutes and progressing to new Q waves. Those not accepted in the study were (1) patients who had symptoms of more than 12 hours at entry into the coronary care unit, (2) patients with recurrent infarction of a previously infarcted area, and (3) patients older than 75 years. No patient was excluded from invasive therapy because of poor hemodynamic condition. All patients gave written informed consent after detailed explanation of the procedure, its possible hazards, and possible beneficial effects.

Cardiac catheterization: Patients were studied with selective coronary arteriography using the femoral percutaneous technique. They were given heparin, 7,500 U intraarterially, and prednisolone, 250 mg intravenously, in order to prevent allergic reactions to streptokinase. Diazepam and morphine sulfate were administered when necessary. Before use of contrast material left ventricular pressure was recorded during mid-inspiratory apnea (8F catheter, Statham P23db transducer). Monoplane left ventricular cineangiography was performed in the 30° right anterior oblique projection (40 ml Urografin 76®, 35 mm cinefilm, 50 frames/s, Philips dual field 9-5 inch image intensifier system). Selective arteriography of the right and left coronary artery (by manual injection) was performed in 6 projections including 3 hemiaxial projections. When a coronary occlusion was clearly visualized, intracoronary injection of 0.2 to 0.4 mg of nitroglycerin was performed to exclude spastic occlusion; thereafter continuous infusion of streptokinase (2,000 U/min) was begun with the coronary catheter in the coronary ostium. Contrast material injections were repeated every 15 minutes and the infusion was stopped 15 minutes after reperfusion. If the coronary vessel was not reopened after infusion of 200,000 U of streptokinase, the attempt was given up. Thereafter the patient was transferred to the coronary care unit.

Patient care: Patients were treated with bed rest. Administration of intravenous heparin was begun according to thrombin time to achieve therapeutic anticoagulation (prolongation of thrombin time to 2 to 3 times normal value). This therapy was followed by oral sodium warfarin. A routine 12

* $p < 0.05$ versus value in group A1.

lead electrocardiogram was obtained daily in the coronary care unit. Serum creatine kinase activity was determined hourly for 12 hours and every 4 hours for the following 36 hours.[8] (The normal range of serum creatine kinase activity is up to 80 U/liter.[8]) Patients left the coronary care unit after 4 to 5 days. Left ventricular and coronary angiography were repeated 4 weeks after the acute event using premedication with diazepam, 10 mg orally. Great care was taken to obtain identical views of left ventricular angiograms at baseline and after 4 weeks (the C-arm was equipped with a scale of 360°). Patients were discharged from the hospital 1 day later.

Analysis of angiograms: The angiograms were interpreted independently by 2 experienced observers. From the coronary arteriograms obstructions were determined and collateral circulation to the distal vessel segment (the infarct vessel before recanalization) was carefully noted. Coronary anatomy was scored as suggested by Gensini,[9] and scores were calculated for all coronary vessels and for the infarct vessel. Estimates of the severity of coronary anatomy by 2 observers were highly correlated ($r = 0.90$, $n = 60$). End-diastolic, end-systolic, and stroke volumes were determined[10] from the left ventricular angiograms, and both the ejection fraction and the regional ejection fraction were calculated. The regional ejection fraction was determined with use of the area method of Gelberg et al.[11] The area system measured systolic change as area reduction (in percent of end-diastolic area). Areas corresponding to the perfusion area of the infarct vessel were averaged (anterior infarction: areas 1, 2, and 3; inferior infarction: areas 3, 4, and 5 [Fig. 1]). Normal areas were also averaged. To minimize bias in the tracing of the ventriculogram for a patient after 4 weeks, outlines were obtained in early and late batches with the patient order randomized in each batch. The early ejection fraction was measured by 2 experienced observers independently in 15 patients (without clinical and arteriographic outcome), and comparison of data revealed a correlation coefficient of $r = 0.93$. The regional ejection fraction was measured in 26 regions by the same 2 independent observers, and results showed a correlation coefficient of 0.93. Left ventricular end-diastolic pressure was measured at the junction of the a wave with the upstroke of ventricular pressure.

Statistical analysis: Analysis of variance, the Student-Newman-Keuls test, and the chi-square procedure (Brandt-Snedecor) were used.[12] Differences were considered significant if the probability (p) was less than 0.05. Mean values ± standard deviation are given in the tables and the Results section.

Results

Comparability of groups: Fifteen patients had successful recanalization of the infarct vessel within 4 hours (group A1) after the onset of symptoms, 17 patients had recanalization after more than 4 hours (group A2), and in 7 patients the attempt to recanalize failed (group B). The average age of patients in group A1 (2 women, 13 men) was 55 ± 10 years, in group A2 (2 women, 15 men) 55 ± 10 years, and in group B (7 men) 50 ± 9 years (Table I). At initial clinical examination 11 patients in group A1 were in Killip class I, 3 were in class II, and 1 was in class III[7]; 12 patients in group A2 were in class I, 3 in class II, and 2 in class III; and 6 patients in group B were in class I and 1 patient was in class III. One patient had cardiogenic shock (characterized by central systolic arterial blood pressure less than 90 mm Hg, evidence of peripheral hypoperfusion, urinary flow below 20 ml/hour, pulmonary wedge pressure of 15 mm Hg or greater, and a cardiac index of 2.3 liters/min per m^2 or less) within 24 hours after the onset of symptoms. Anterior, anterolateral, and anteroseptal infarctions were categorized as anterior infarctions and were found in 8, 7, and 3 patients of groups A1, A2, and B, respectively; inferior, inferolateral, and inferoposterior infarctions were categorized as inferior infarctions and were found in 7, 10, and 4 patients of groups A1, A2, and B (Table I). A history of previous infarction was present in 2 patients each in groups A1 and A2 and in 1 patient in group B.

The time lag between onset of symptoms and recanalization of infarct vessel was 3 hours 10 minutes in group A1 and 5 hours 52 minutes in group A2. The baseline Gensini score for all coronary vessels and for the infarct vessel, localization of the infarct vessel, collateral supply to the infarct vessel, left ventricular pressure, left ventricular end-diastolic volume, ejection fraction, regional ejection fraction of the infarct area, and serum creatine kinase activity were comparable among the 3 groups (Table I). The heart rate at the beginning of cardiac catheterization was significantly higher ($p < 0.05$) in group A2 than in group A1. In group A1, 11 of 15 patients had total occlusion of the infarct

Peak serum creatine kinase activity (U/liter)	764 ± 403	1,580 ± 877*	2,106 ± 1,699*

* $p < 0.05$ versus value in group A1. † $p < 0.05$ versus value in group A2.

vessel but 4 had subtotal occlusion (99%) with poor runoff. Success was defined as reopening of occlusion with good runoff or marked improvement of runoff in cases of subtotal occlusion. In group A2, 13 of 17 patients had total occlusion and 4 patients subtotal occlusion of the infarct vessel ($p > 0.05$).

Duration of ischemia versus late results 4 weeks after thrombolysis: At restudy in group A1, the recanalized infarct vessel was found open (but stenosed) in 12 of 15 patients; the patient with early bypass grafting had an open graft, and the remaining 2 patients who had reinfarction showed reocclusion of the infarct vessel. In group A2 the infarct vessel was open (with stenosis) in 12 patients; the 2 patients with early bypass grafting had an open graft, the patient with early transluminal angioplasty had 50% stenosis, and 2 patients had reocclusion of the infarct vessel. In group B, 1 of 7 patients had spontaneous recanalization of the infarct vessel at restudy, but the remaining 6 patients had an occluded infarct vessel.

The Gensini score of the infarct vessel was significantly lower after 4 weeks in groups A1 and A2 after recanalization than in group B (Table II). The ejection fraction was significantly higher in group A1 than in the other 2 groups. Similarly, the regional ejection fraction of the infarct area was higher in group A1 than in both the other groups (Table II). Serum peak creatine kinase activity increased from group A1 to group A2 and group B (Table II). The dose of streptokinase, the Gensini score of all coronary vessels, left ventricular pressure, and the regional ejection fraction of the normal area did not differ between groups. Left ventricular end-diastolic volume was lower in group B than in group A2.

Hospital course and late follow-up study: Patients were hospitalized for 4 weeks after infarction. Recurrence of infarction by clinical and enzymatic criteria was observed in 2 patients in group A1 and in 2 patients in group A2. The interval between initial infarction and recurrence of infarction was 1 day, respectively, 7 days in group A1 and 10, respectively, 15 days after initial infarction in group A2. Coronary bypass surgery was performed the day after successful recanalization in 1 patient in group A1 and in 2 in group A2. Percutaneous transluminal angioplasty was performed in 1 patient in group A2 two days after successful recanalization. Complications of the procedure were minor bleeding at the puncture site in 4 patients and gastrointestinal bleeding in 1 patient. The patients in group A1 were followed up for 13.9 ± 5.8 months (range 6 to 24), patients in group A2 for 9.9 ± 7.6 months (range 2 to 23), and patients in group B for 11.0 ± 3.2 months (range 7 to 16). Five patients in group A1 and 2 in group A2 had undergone aortocoronary bypass because of disabling angina 2 to 6 months after infarction. No patient in group A1 but 3 patients in group A2 and 1 in group B died during the late follow-up period.

Discussion

The data of the present study show that reperfusion after a short duration of ischemia (group A1) exerts a beneficial effect: A higher ejection fraction, regional ejection fraction of the infarct area, and a lower serum peak creatine kinase activity were found in this group than in the group with reperfusion after a long duration of ischemia (group A2), or in the group without reperfusion (group B). The 3 groups were comparable according to the following criteria: (1) the state of coronary vessels, especially of the infarct vessel as evaluated by the Gensini score; (2) the localization of infarctions; (3) regional and overall left ventricular function as determined by invasive study; (4) clinical class at entry into the coronary care unit; and (5) normal serum creatine kinase activity before invasive study. Thus, comparability of the 3 groups before thrombolytic therapy was documented by invasive and noninvasive data.

The diagnosis of acute transmural myocardial infarction was mainly based on persistent S-T segment elevation and development of new Q waves. DeWood et al.[2] found that persistent (as opposed to transient) major S-T segment elevation greater than 2 mm led to transmural infarction (as estimated from the development of new Q waves) in more than 98% of 232 patients. The present study accepted only patients with S-T segment elevation of at least 2 mm in at least 3 leads of the standard 12 lead electrocardiogram persisting for more than 30 minutes.

In experimental studies it has been shown that infarct size was determined by (1) the duration of ischemia,[3] (2) the collateral flow to ischemic area,[13] and (3) the size of the perfusion area of the infarct vessel.[14,15] The present study assessed differences in the duration of ischemia (coronary occlusion) before reperfusion in a series of patients in whom collateral flow to the ischemic area and size of the perfusion area as estimated by the Gensini score were found comparable. The duration of ischemia is a major determinant of infarct size and early mortality after coronary arterial reperfusion in dogs.[3,16] Various studies have estimated myocardial infarct size and myocardial function after different time lags between coronary occlusion and reperfusion. Most studies report salvage of ischemic myocardium after coronary arterial reperfusion when compared with animals with permanent coronary arterial ligation. The recovery of myocardial function after early reperfusion (1, 2, or 3 hours after coronary occlusion) was protracted and was generally seen only 1 to 4 weeks after the start of reperfusion, but not immediately thereafter.[17–20] When late reperfusion was instituted after 5 or 6 hours of coronary occlusion, recovery of myocardial function was only minimal.[21] When pigs were studied instead of dogs, the beneficial effect of early reperfusion (after 1 hour of coronary arterial occlusion) was less pronounced: Althaus et al.[22] reported no significant difference in infarct size after coronary occlusion in the pig when reperfusion was instituted after 1 hour of coronary occlusion, but only less aneurysmal formation than in animals with permanant coronary occlusion. This lack of a beneficial effect on infarct size was attributed to the lack of adequate collateral circulation in the pig.

Coronary collateral vessels were found in the present study in about 50% of cases in all 3 groups. The collateral supply to ischemic myocardium modifies the association

between the duration of myocardial ischemia and necrosis because collateral flow improves the tolerance of the myocardium against ischemia.[13]

The size of the perfusion area was assessed by the Gensini score, which incorporates the size of territory of a coronary vessel. The Gensini score of the infarct vessel was comparable among the 3 groups, suggesting comparable areas at risk.

Differences in peak creatine kinase activity showed inverse behavior as compared with differences in regional ejection fraction of the infarct area 4 weeks after thrombolysis: Patients with early reperfusion (group A1) had a higher regional ejection fraction and lower peak creatine kinase activity than patients with late reperfusion (group A2). The same was true when data in groups A1 and B were compared. Peak creatine kinase activity was taken as an estimate of myocardial necrosis after reperfusion, because close agreement between enzymatic and histologic extent of infarction was described after experimental reperfusion of infarction.[23] Creatine kinase activity may be disproportionally elevated after reperfusion at a given infarct size as compared with permanent occlusion. Irrespective of these differences in the washout of enzymes, it is evident from the data that early reperfusion produces smaller enzymatic estimates of infarct size than does late reperfusion.

Limitations and implications of the study: The beneficial effect of early reperfusion within 4 hours was shown by comparison with a group that was reperfused after 4 hours of ischemia. Early reperfusion produced smaller infarcts (creatine kinase activity) and better contraction of the infarct region than late reperfusion. Whether late reperfusion has any beneficial effect cannot be answered by the present study: there were only small differences between the group with late reperfusion and the group without reperfusion.

The present study is retrospective. Although the 3 groups are similar in a number of clinical variables and angiographic data, some possible errors cannot be ruled out: Patients who could not undergo recanalization may represent a different type of coronary occlusion (intimal hemorrhage or dissection) than patients who could undergo recanalization (thrombosis). Furthermore, patients who had early reperfusion had a lower heart rate than patients with late reperfusion, and hence myocardial oxygen consumption during occlusion may have been lower in these patients. Because the data presented showed such a highly significant and clinically relevant reduction in infarct size after early as compared with late reperfusion (and permanent coronary occlusion), we do not feel encouraged to undertake a randomized trial to examine more precisely the duration of ischemia before reperfusion versus late results in patients with acute transmural myocardial infarction suited for thrombolysis. Randomization would require postponement of the recanalization attempt in several patients. However, the data presented show that the time lag between the onset of symptoms and reperfusion is clinically the most important determinant of the therapeutic success of recanalization in acute transmural myocardial infarction.

Sulfinpyrazone Decreases Epinephrine-Induced Platelet Aggregation After Myocardial Infarction

JEAN-GILLES LATOUR, PhD, PIERRE THEROUX, MD, and MARTIAL G. BOURASSA, MD

Platelet studies were performed during a controlled double-blind randomized clinical trial of sulfinpyrazone (Anturane Reinfarction Trial) in 41 patients who had recent myocardial infarction. Aggregation of platelet-rich plasma by thrombin (0.185, 0.246 U/ml), collagen, adenosine diphosphate, and adrenaline (0.23, 0.46, and 0.91 μg/ml) was estimated after a 12 hour fast including abstinence from drugs and cigarette smoking. The tests were carried out 2 weeks after myocardial infarction and 6, 12, and 24 months later. At the last visit, washed platelet suspensions were also tested for aggregation to thrombin (0.03, 0.015 U/ml) ± epinephrine (0.55 μg/ml) and their production of malonyldialdehyde was estimated. A significant ($p < 0.02$) reduction (50%) of the aggregation response of platelet-rich plasma to epinephrine was found in the group treated with sulfinpyrazone ($n = 21$) as compared with the placebo group ($n = 20$). Also, adrenaline evoked a milder ($p < 0.01$) potentiation of aggregation by thrombin of the washed platelet suspensions in the sulfinpyrazone versus the placebo group. Other assays including platelet coagulant activity were not useful in discriminating between the 2 groups. It is concluded that sulfinpyrazone (200 mg 4 times daily) normalizes the platelet response to epinephrine; a relation with the drug-reported reduction of sudden death after myocardial infarction is suggested.

Platelet involvement in vascular and thrombotic processes is well recognized, and the potential benefits of drugs interfering with platelet function have led to several clinical trials in the last decade.[1] Sulfinpyrazone has received special attention in this regard. In contrast to aspirin, sulfinpyrazone reduces platelet turnover and prolongs platelet survival in patients with gout,[2] prosthetic heart valves,[3] mitral valve prolapse,[4] coronary artery disease,[5] rheumatic heart disease,[6] recurrent venous thrombosis,[7] and hyperbetalipoproteinemia.[8] The mechanism of these changes is not yet fully understood, but sulfinpyrazone inhibits platelet aggregation and the release reaction in vitro,[9–11] decreases platelet coagulant activity,[12] reduces adherence of platelets to subendothelial structures,[13,14] and protects the endothelium from damage.[15] Although conflicting results have emerged with regard to the ability of the drug to inhibit aggregation in vivo at therapeutic regimens,[3,16–18] prolonged competitive and reversible inhibition of arachidonic acid-induced aggregation and prostaglandin synthesis has been reported.[10,19,20]

Platelet hyperaggregability has been reported in coronary artery disease and myocardial infarction by several investigators,[21,22] but the observations were often limited to adenosine diphosphate and collagen. However, we found that patterns of platelet hyperaggregability differ in the various forms of ischemic heart disease, and examples are the selective platelet hyperresponsiveness to thrombin of young patients with myocardial infarction and angiographically normal coronary arteries and the characteristic platelet hypersensitivity to epinephrine of patients with variant angina.[23,24]

Whether the foregoing platelet changes are primarily or secondarily involved in the process of myocardial infarction and coronary vasospasm is still open to question. In the present study, we took advantage of our participation in the Anturane Reinfarction Trial[25] to carry out platelet function tests and to attempt to correlate platelet changes with the clinical issues of the study. A preliminary report was issued previously[26] and complete data are now presented.

TABLE I Clinical Data

Variable	Patients With Sulfinpyrazone			Patients With Placebo	
Age					
Range (yr)	47–62			45–62	
Mean ± SE	55.6 ± 1.5			53.7 ± 1.3	
Sex					
F	2			3	
M	19			17	
Days (n) post-MI at entry in the study					
Range	28–35			25–35	
Mean ± SE	30.0 ± 0.5			30.1 ± 0.6	
Cigarette smoking	15 (12)			15 (13)	
Hypertension (>150/100 mm Hg)	4			0	
Diabetes mellitus	1			2	
Serum cholesterol (mg/dl)					
Mean ± SE	225 ± 7	(239 ± 9)		238 ± 15	(230 ± 9)
Patients >250	8			9	
Serum triglycerides (mg/dl)					
Mean ± SE	206 ± 17	(220 ± 18)		229 ± 19	(219 ± 16)
Patients > 150	12			10	
Serum uric acid (mg/dl)					
At entry (0)	6.6 ± 3			6.5 ± 3	
After 6 mo	2.9 ± 0.1		$p < 0.001$	6.7 ± 3	
After 12 mo	2.7 ± 0.2		$p < 0.001$	6.3 ± 3	
Patients (n) taking:					
Propranolol	8			13	
Isosorbide dinitrate	3			6	
Hydrochlorothiazide	4			1	
Digoxin	3			2	
Furosemide	2			2	
Diazepam	1			3	
Allopurinol	1			1	
Various other drugs	5			6	
Recorded deaths	1 (MI; 22 mo)			1 (MI; 13 mo)	
Patients withdrawn	0			1 (Hodgkin's)	

Values 1 year after inclusion in the study are given in parentheses. MI = myocardial infarction; SE = standard error of the mean.

Methods

Patients: Of the 107 patients with recent myocardial infarction enrolled in the Anturane Reinfarction Trial at the Montreal Heart Institute, 41 were allocated at random for platelet aggregation and blood follow-up studies. The reader is referred to the description of the multicenter trial[25] for details concerning patient eligibility and procedures. At the end of this double-blind randomized study, 21 patients had received sulfinpyrazone, 200 mg 4 times a day. Of the 20 patients who were given a placebo, 1 was withdrawn from the study after having completed the 1st year, because of Hodgkin's disease.

The clinical data on our patients are summarized in Table I. No difference was observed between the 2 groups with regard to time of enrollment after myocardial infarction, age, sex, smoking habits, serum cholesterol, serum triglycerides, and serum uric acid at the beginning of the study. However, 4 patients in the sulfinpyrazone group had elevated blood pressure. Of the drugs used concomitantly, propranolol was the most commonly prescribed with 8 and 13 patients, respectively, in the sulfinpyrazone and the placebo groups.

Four predetermined laboratory visits were chosen for our study. They corresponded to the time of enrollment before the start of the double-blind medication (indicated as 0 month in illustrations and tables) and to 6, 12, and 24 months after the onset of therapy. Blood was collected between 8:00 and 9:00 A.M. from a forearm vein in syringes containing the appropriate anticoagulant solutions, after a 10 to 12 hour fast including abstinence from drugs and smoking. The samples were drawn at the same time as those for the routine analyses established in the trial, including blood lipids and serum uric acid; these tests were carried out by a central laboratory and the results were not made available to the investigators until completion of the trial. Informed consent was obtained from each subject for the supplementary investigations they underwent in the scope of the present study.

Laboratory investigations: Aggregation of platelets was tested on platelet-rich plasma at each visit, according to methods previously described.[24] Aggregating agents and their final concentrations in the samples were as follows: adenosine diphosphate 0.228, 0.455, and 0.91 μg/ml (Sigma Chemicals, St. Louis); topical bovine thrombin, 0.185 and 0.246 U/ml; adrenaline chloride 0.228, 0.455, and 0.91 μg/ml (Parke-Davis, Detroit) prepared in tyrode-albumin solution; and collagen, 0.228, 0.455, and 0.91 μg/ml dissolved in glacial acetic acid.

The citrated platelet-rich plasma was obtained by centrifugation and the platelet counts were adjusted to $350 \times 10^3/\mu l$. The tests were initiated by the addition of 50 μl of the reagent to 500 μl of platelet-rich plasma on a Payton Dual Channel aggregometer at 37°C. The aggregation response was recorded for more than 3 minutes and the curves were computed on a Hewlett-Packard Calculator 9830A with digitizer, for analysis of the speed of aggregation (maximal slope of the reaction; 1 cm/cm = 10% transmission/0.5 min), extent of aggregation (surface under the curve; 1 cm^2 = 5% transmission-minute), and magnitude of aggregation (maximal amplitude of the curve; 1 cm = 10% transmission). These calculations were performed 1 minute after the addition of thrombin and 1 and 3 minutes after adenosine diphosphate and epinephrine for estimation of the primary and secondary waves of aggregation, and after 3 minutes with collagen.

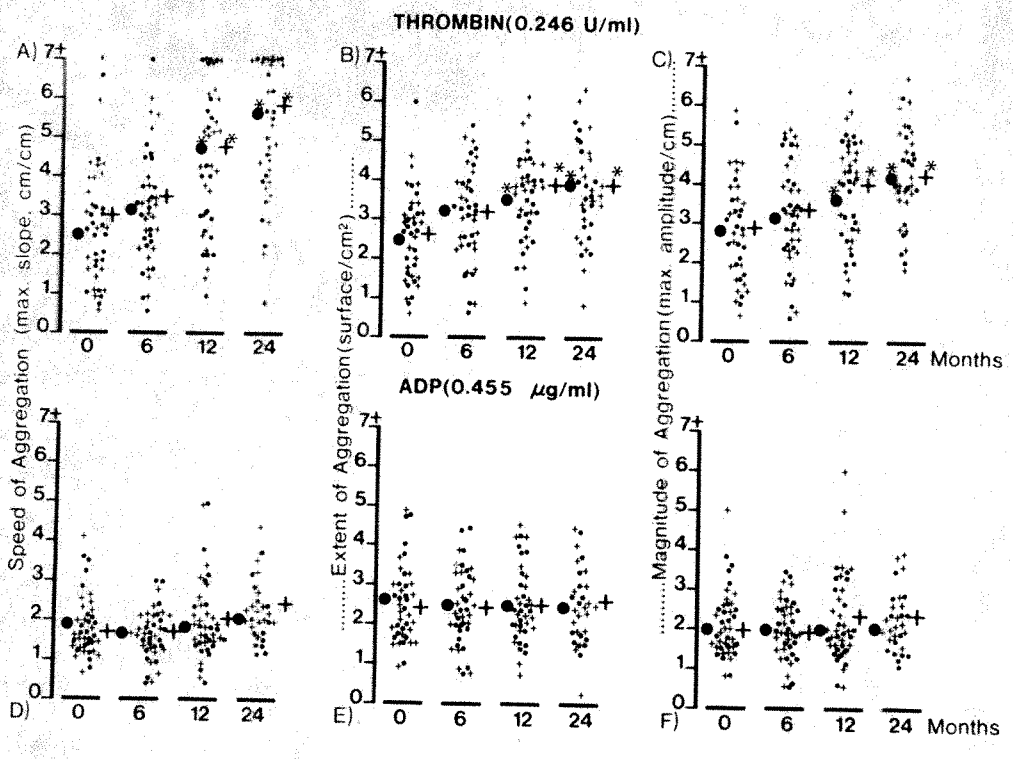

FIGURE 1. Platelet aggregation follow-up data: responses of platelet-rich plasma to thrombin and adenosine diphosphate (ADP). **Large signs** indicate means.

At the last visit after 2 years of treatment, aggregation to thrombin (0.015 and 0.030 U/ml) in the absence or presence of epinephrine (0.55 μg/ml) was also estimated on washed platelet suspensions (350 × 10^3 platelets/μl) prepared from acid-citrate-dextrose anticoagulated blood.[24]

Production of malonyldialdehyde was also estimated after stimulation of the washed platelet suspensions with 2.7, 0.68, and 0.34 U of thrombin/ml ± epinephrine (0.55 μg/ml) according to the method of Smith et al.[27] modified by Zucker.[28] One milliliter of the platelet suspension incubated at 37°C and stirred at 900 rpm was challenged with 100 μl of the aggregant. The reaction was stopped after 3 minutes by the addition of 1.1 ml of trichloroacetic acid. Malonyldialdehyde was estimated after reaction with 2-thiobarbituric acid.[29,30] The results were expressed in nanomoles of malonyldialdehyde/10^9 platelets. Normal reference values were obtained from a group of 20 normal healthy volunteers aged 20 to 48 years (mean 30 years) recruited among the hospital staff.

Platelet coagulant activity and cephalin clotting times were estimated at the first 2 visits according to platelet unactivated and collagen activated systems. As reported previously,[31] a Biodynamics coagulometer coupled to a recording system was used to evaluate the clotting times, as evidenced by changes in optical densities. The basic unactivated test consists in a modification of the plasma recalcification time[32]: 100 μl of platelet-rich plasma (120 × 10^3 platelets/μl) is incubated during 5 minutes at 37°C with 100 μl of tris-buffered saline solution. Saline solution (20 μl) is added and the incubation prolonged for exactly 60 seconds followed by the addition of 100 μl $CaCl_2$, M/50. In the activated system, collagen (20 μg; Sigma Chemicals, St. Louis) homogenized in saline solution is substituted for the 20 μl of saline solution. Assay of the cephalin time is carried out by replacement of platelet-rich plasma by platelet-poor plasma (less than 2 × 10^3 platelets/μl) and of a 1/100 diluted rabbit brain cephalin extract[33] instead of 100 μl of tris-buffered saline solution. Plasma prekallikrein was measured on citrated plasma by use of a 2-stage esterolytic assay described in detail elsewhere.[34]

Statistics: Unless specified, Student's *t* test for comparison of means and a level of significance of 0.05 were used for statistical analysis. In addition, as indicated in the text, the *t* test method for paired comparisons was also utilized.

Results

Clinical data: As shown in Table I, no significant change was observed in serum levels of cholesterol and triglycerides after 1 year, and a similar number of patients stopped smoking in both groups. Two deaths were recorded during the study, 1 in each group, and both followed recurrent myocardial infarction.

As expected, serum uric acid levels were greatly reduced in all patients given sulfinpyrazone, the mean reduction being close to 60% ($p < 0.001$) for the group. Except in 4 cases, 2 in each group, who at one time during the study showed values incompatible with the mode of therapy (levels unchanged with sulfinpyrazone and reduced by 50% with placebo), analysis of the individual serum uric acid patterns showed compliance to the double-blind drug regimens and all the results were included in our final analysis.

Laboratory data: Aggregation (speed, extent, and magnitude) of platelet-rich plasma induced by thrombin was equivalent in the 2 groups throughout the study (Fig. 1). However, the response increased in a gradual

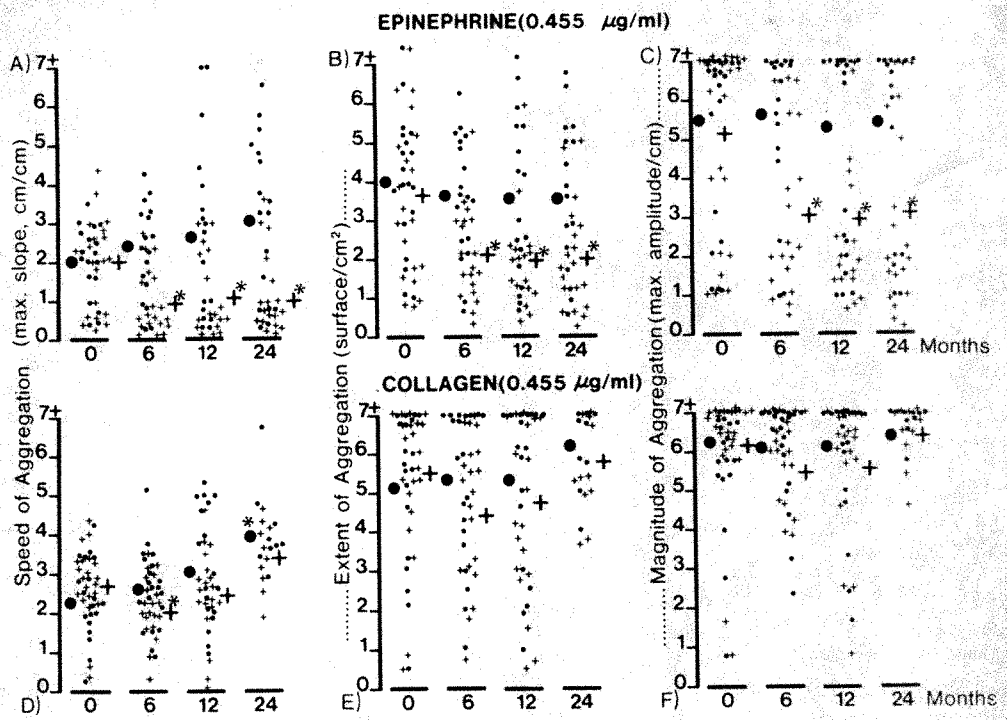

FIGURE 2. Platelet aggregation follow-up data: responses of platelet-rich plasma to epinephrine and collagen. **Large signs** indicate means.

and similar manner in both the placebo and sulfinpyrazone group and the changes reached statistical significance ($p < 0.05$) after 12 and 24 months; the increases were also significant ($p < 0.05$) after 6 months when paired t test comparisons were made. These results contrast with those obtained with adenosine diphosphate. Both groups responded equally to adenosine diphosphate, and no change whatsoever was measured during the study at all the concentrations tested.

The response of platelet-rich plasma to epinephrine and collagen is illustrated in Figure 2. At no time was a measurable change in platelet response to epinephrine observed in the placebo group. In contrast, a 40 to 50% ($p < 0.05$) reduction in the speed, extent, and magnitude of aggregation was noted in the sulfinpyrazone-treated group. The placebo and sulfinpyrazone groups differed statistically at 6, 12, and 24 months. Maximal reduction of aggregation was reached after 6 months and remained constant thereafter. The reduction of aggregation involved mainly the secondary wave of aggregation but also the primary wave. Analysis of aggregation responses 1 minute after addition of epinephrine, a time when the secondary response had not yet taken place, revealed a significant ($p < 0.02$, t test for paired comparisons) reduction from pretherapeutic aggregation responses. Typical epinephrine-induced aggregation curves in a patient with platelet hyperaggregability and treated with sulfinpyrazone are shown in Figure 3.

With regard to collagen, the speed of aggregation slightly increased ($p < 0.05$ after 1 year; paired t test) in the placebo group, but the extent and magnitude of aggregation remained unchanged. However, in the sulfinpyrazone group, aggregation to collagen was mildly decreased. Nevertheless, the 2 groups were statistically similar in their response to collagen aggregation during the entire study.

The aforementioned significant changes in platelet aggregation to thrombin and epinephrine were not related to propranolol therapy. Patients receiving propranolol at the time of their admission to the project had an enhanced aggregation to all reagents tested ($p < 0.02$ for thrombin and adenosine diphosphate) as compared with patients not taking the drug. Despite this, we observed a similar decrease (45%) in aggregation to epi-

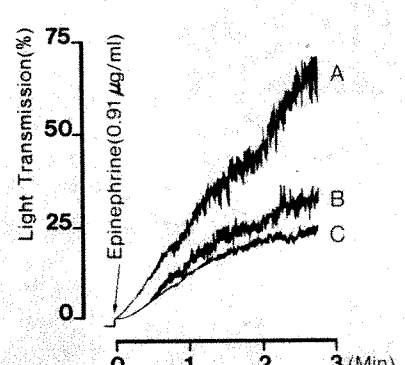

FIGURE 3. Typical aggregation responses of platelet-rich plasma to epinephrine in a patient with hyperaggregability before sulfinpyrazone (A) and after 6 (B), 12, and 24 months (C).

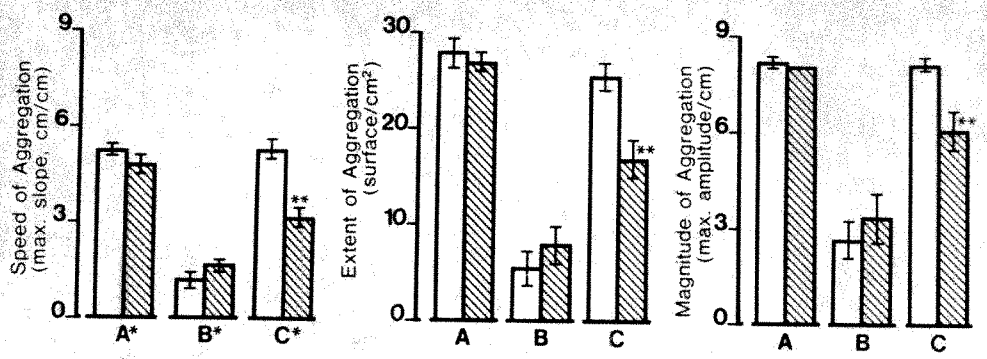

FIGURE 4. Aggregation of washed platelet suspensions by thrombin and its potentiation by epinephrine; effect of sulfinpyrazone.

nephrine and a similar increase (50%) in aggregation to thrombin in subgroups of patients taking sulfinpyrazone alone (n = 13) or in association with propranolol (n = 8). Because of the limited number of patients taking other drugs (Table I), their possible effects could be evaluated only on an individual basis; no detectable effect was observed.

Thrombin (0.03; 0.015 U/ml) elicited similar aggregation responses on washed platelet suspensions from placebo- and sulfinpyrazone-treated groups (Fig. 4). However, in the group receiving sulfinpyrazone, the potentiation effect by epinephrine at a low concentration (0.015 U/ml) of thrombin was about half ($p < 0.01$) that measured in the placebo group. On the other hand, thrombin induced production of malonyldialdehyde in a dose-related manner, from 5.8 nmol/10^9 platelets with 0.34 U/ml of thrombin to 8.6 nmol with 2.7 U/ml, and to the same extent on platelet suspensions from the sulfinpyrazone and placebo patient groups (Fig. 5). Also, the addition of epinephrine (0.55 μg/ml) to a low dose of thrombin (0.34 U/ml) yielded an additional production of malonyldialdehyde (0.48 nmol; $p < 0.05$, *t* test for paired comparisons) that was identical in suspensions prepared from the placebo- and sulfinpyrazone-treated groups. Although the 2 patient groups could not be dissociated from each other in terms of their platelet production of malonyldialdehyde, their response was 30% ($p < 0.01$) greater than that measured in a normal control group under similar conditions.

No significant change was found in platelet coagulant activity after 6 months of therapy in the sulfinpyrazone and placebo groups. As shown in Table II, clotting times of recalcified platelet-rich plasma in the presence or absence of collagen were within the same range in both groups. Activation of the platelets by collagen shortened by 60% the clotting time of platelet-rich plasma in both groups without significant modification of the cephalin clotting time. Neither of the 2 tests discriminated between the 2 groups.

Plasma prekallikrein (Table III) declined gradually but very slightly in the sulfinpyrazone group. The reduction was significant ($p < 0.05$; *t* test for paired comparisons) after 1 and 2 years of therapy. However, the change was so small that the placebo- and sulfinpyrazone-treated groups could not be dissociated from each other on a statistical basis.

Discussion

Ex vivo measurements of platelet aggregation indicate that sulfinpyrazone, 200 mg 4 times a day, does not produce a generalized and sustained inhibition of platelet aggregation in man. Of the 4 aggregating reagents known to interfere with hemostasis in vivo, and used here in vitro at different concentrations to produce

minimal to maximal aggregation, only the response to epinephrine was significantly modified by sulfinpyrazone as compared with placebo.

The observed reduction (50%) in epinephrine-induced aggregation can be interpreted as a normalizing effect of sulfinpyrazone therapy on platelet sensitivity to catecholamines rather than as a specific inhibition of aggregation, and can be compared with the reported prolongation of platelet survival time produced by the drug in several clinical states.[2–7] An initial observation supporting this hypothesis is that complete inhibition of the epinephrine response was not encountered in any of our patients and that the mean response elicited by epinephrine in patients receiving sulfinpyrazone was identical to that previously reported in untreated normal volunteers, using the same methods.[24] Therefore, it appears that sulfinpyrazone simply corrected the hyperreactivity of platelets to epinephrine which was present in both groups at the start of the study and remained unchanged thereafter in the placebo group.

A second argument favoring the idea of a normalization process is that the washed platelet suspensions obtained from the sulfinpyrazone-treated patients were much less sensitive to the potentiating effect of epinephrine on a low concentration of thrombin, although inhibition of aggregation by sulfinpyrazone is cleared by reversible and competitive[10] and the washing process for preparation of platelet suspensions.[35] An additional indication derives from the observation that although reduction of the epinephrine response primarily involved the secondary wave aggregation, the primary wave was nonetheless significantly attenuated by sulfinpyrazone therapy. It is generally accepted that the primary wave of aggregation induced by epinephrine is mediated by stimulation of the alpha-adrenergic receptors and prevented by alpha-adrenergic blocking agents,[36] whereas secondary aggregation results from the release of platelet constituents, mainly endoperoxides and thromboxane A_2.[37] However, a similar production of malonyldialdehyde was measured after the addition of epinephrine and thrombin to platelet suspensions from both the sulfinpyrazone and placebo groups, indicating that inhibition of prostaglandin synthesis was not involved in the observed reduction of platelet aggregation to epinephrine in our sulfinpyrazone-treated patients. This result differs from those reported with arachidonic acid-induced aggregation.[19,20] Therefore, another mechanism must also be involved; it is unlikely to be another factor in the release reaction because no significant inhibition was measured with low concentrations of thrombin and collagen in the sulfinpyrazone group.

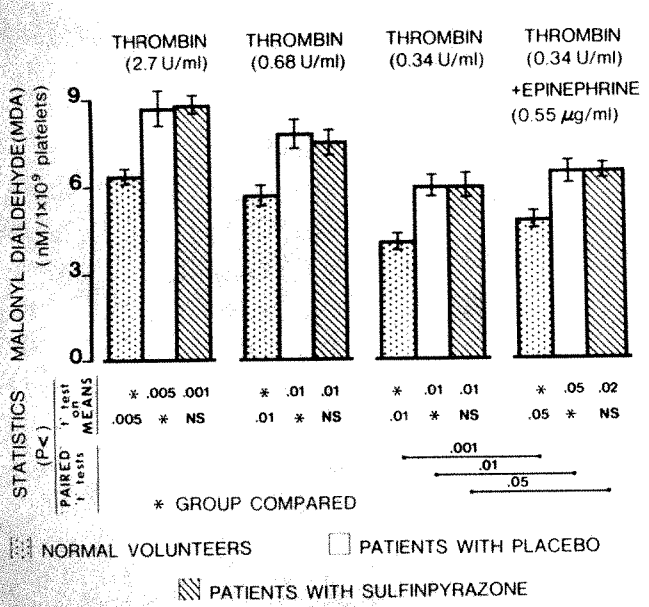

FIGURE 5. Malonyldialdehyde production by washed platelet suspensions stimulated with thrombin and thrombin + epinephrine.

TABLE III Effect of Sulfinpyrazone Therapy on Plasma Prekallikrein

Groups	Prekallikrein (μM, TAME Hydrolyzed/h/ml plasma) 0 (entry)	6 mo	12 mo	24 mo

Placebo	112.2 ± 4.4	110.1 ± 3.1	109.3 ± 3.7	109.6 ± 3.7

* $p < 0.05$ versus values at entry in the project (paired t test analysis).

Additional evidence that normalization rather than inhibition of the platelet response to epinephrine may have taken place can be drawn from the observation that platelet aggregation to epinephrine in man is not modified 2 hours after administration of a single dose of sulfinpyrazone nor after 4 days of treatment as in the present study.[16] Therefore, our observation made after 6 months of sulfinpyrazone therapy and 10 hours after the last intake of the drug is apparently the result of sustained and long-term treatment.

Platelet aggregation induced by thrombin in platelet-rich plasma was far greater than normal[24] at the onset of the study and kept increasing gradually in the following 2 years in both groups of patients. Increased aggregation to thrombin has been associated with a higher risk of thrombosis[38] and myocardial infarction[24], and the observed failure of sulfinpyrazone to control the hyperaggregability to thrombin in our patients is possibly related to the reported ineffectiveness of the drug in preventing recurrence of myocardial infarction in the Anturane Reinfarction Trial.[25] However, the platelet hyperresponsiveness to thrombin in our patients was not the result of intrinsic platelet changes as we previously reported in young patients with myocardial infarction and normal coronary arteriograms,[24] but rather was due to plasma environmental changes as indicated by the normal response of the washed platelet suspensions to thrombin.

In accordance with Cortellaro et al.[39] we found no significant difference between the placebo and sulfinpyrazone groups in platelet response to adenosine di-

phosphate. However, a slight decrease was seen in response to collagen in the sulfinpyrazone group, suggesting a weak effect of the drug. However, the 2 groups of patients remained identical on a statistical basis. Release or availability of platelet coagulant material (Table II) and plasma prekallikrein (Table III) was not modified by the sulfinpyrazone regimen. This last observation contrasts with the results reported in patients with myocardial infarction and normal coronary arteriograms in whom high levels of prekallikrein were found in association with their tendency to coronary spasm.[24]

The association of propranolol with sulfinpyrazone had no influence on the platelet aggregation response to epinephrine and thrombin. However, when all the patients taking propranolol before the start of the drug trial were, as a group, compared with those not taking the beta-blocking drugs, we found significant ($p < 0.02$) increases in platelet aggregation, particularly to thrombin and adenosine diphosphate. To explain such a result one may question the severity of the disease or the associated factors requiring beta-blockade therapy, but as we previously reported, blockade of the beta-receptors enhances slightly the aggregation of human platelets and strongly those of other species.[36]

In conclusion, normalization or reduction in the platelet response to epinephrine is the only significant observation that distinguished the sulfinpyrazone and placebo groups in this study. This change in platelet response to epinephrine in relation to the reported benefit of the drug in reducing the rate of sudden death after myocardial infarction remains speculative. However, the observation may also indicate an important drug or disease process taking place elsewhere in the organism, with no particular or restrictive relevance to platelets and platelet aggregation. As a matter of fact, sulfinpyrazone has been shown to act on cell membrane, to inhibit in high dosages, like alpha-adrenergic blocking agents, the primary wave of platelet aggregation induced by epinephrine in vitro,[11] to protect the endothelium from damage,[15] and to prevent arrhythmias in isolated rabbit heart preparations.[40]

Familial Aggregation of Coronary Heart Disease and Its Relation to Known Genetic Risk Factors

LEO P. ten KATE, MD, HELGE BOMAN, MD, STEPHEN P. DAIGER, PhD, and ARNO G. MOTULSKY, MD

The question of how much of the familial aggregation of coronary heart disease is explained by familial clustering of coronary risk factors was approached by a case-control study involving 145 white male survivors of myocardial infarction, 145 age-matched white male blood donors, and the first-degree relatives of both groups. Certain risk factors such as serum cholesterol, triglyceride, and fasting blood glucose levels, blood pressure, and smoking history were determined in patients and control subjects. Relatives were interviewed. If the person was deceased, a copy of the death certificate was obtained. With the exception of high blood pressure, risk factors were significantly more frequent in patients than in control subjects.

Among first-degree relatives of survivors of myocardial infarction, 16% had had a myocardial infarction, compared with 8.9% of relatives of control subjects. The frequency of coronary heart disease among first-degree relatives of patients and control subjects was 20.5 and 14.7%, respectively. To find out whether this higher frequency among relatives of patients was fully explained by the existence of known genetic risk factors among survivors of myocardial infarction, 2 approaches were taken. First, statistical analysis that eliminated the role of the various known genetic risk factors (by data stratification according to confounding risk variables and subsequent calculation of a pooled relative risk estimate according to the Mantel-Haenzel method) still indicated an approximately 2-fold (2.14) relative risk for myocardial infarction among families of survivors of myocardial infarction (and a risk of 1.71 for coronary heart disease). Similarly, another approach (Cox's life table regression analysis) confirmed that the classic risk factors could not predict familial occurrence.

These results indicate that the *familial aggregation of coronary heart disease is not entirely explained by the familial clustering of currently known coronary risk factors.* Such familial aggregation could be caused by yet undefined genetic factors, by environmental factors common to family members, or by interaction of genetic factors with environmental agents.

Coronary heart disease and myocardial infarction tend to run in families. In case-control studies the incidence of myocardial infarction in first-degree relatives of patients with myocardial infarction is about 2 to 4 times higher than among first-degree relatives of healthy control subjects.[1-9] The risk for relatives of younger victims of myocardial infarction is higher than for relatives of older patients, although this was not seen in 1 study.[2,6,10] Concordance rates are higher in monozygotic than in dizygotic twins.[11-13] Heritability estimates range from 20 ± 10%[8] to as high as 80%.[14]

Clinical and prospective cohort studies have revealed several variables that predict coronary heart disease and myocardial infarction. Although the causal relations of these variables in coronary heart disease are not yet completely clear, they are generally referred to as risk factors. Well-known major risk factors include smoking, high blood pressure, hyperlipidemia, and diabetes. Some risk factors such as hypertension, hyperlipidemia, and diabetes mellitus clearly have an important genetic component. Clear Mendelian patterns of familial occurrence of coronary heart disease are occasionally observed. The most frequently implicated major gene is that for familial hypercholesterolemia, with a population frequency of 0.1 to 0.5%.[15] However, most instances of familial aggregation of coronary heart disease and myocardial infarction do not conform to monogenic inheritance.

The question arises whether the familial aggregation of coronary heart disease can be fully explained by the presence of currently known major genetic risk factors such as hypertension, hyperlipidemia, and diabetes. The present study provides evidence for familial aggregation apart from that contributed by these risk factors.

Methods

Selection of probands: interview procedures and examinations: Medical records of persons admitted to 5 hospitals in the Seattle area in the years 1974 and 1975 were reviewed to ascertain all male, Caucasian, 30 to 59 year old survivors of myocardial infarction. Criteria for acceptance of the diagnosis were identical to those used in an earlier study.[16] Of the 198 patients identified, 145 were available for our study (see later for reasons of exclusion). The accessible patients were contacted by phone by a field worker. Information was asked about the patient's present health status; his past medical examination, diet, and drug history; his smoking habits; the family structure; and the names and phone numbers of his first-degree relatives and their willingness to cooperate in the study.

Voluntary blood bank donors from the Puget Sound Blood Center in the years 1977 and 1978 were invited to participate in a study of familial chronic disease until 145 male Caucasian control subjects age-matched with the 145 patients had been found. No mention was made of our interest in heart disease. The policy of the Blood Center was to exclude from donations diabetic patients on insulin treatment, epileptic patients and persons taking beta blocking agents or antibiotic drugs (except for acne treatment), as well as those with a blood pressure exceeding 180/100 mm Hg (after rest). Other reasons for exclusion from the study were a history of hepatitis or any known contact with hepatitis, and work with blood or blood products. Medical personnel, persons with blood disorders, ill persons, and those who had undergone major surgery in the last 6 months were also excluded. Persons taking oral antidiabetic, antihypertensive, antidiuretic, or antihyperlipidemic agents were *not* excluded.

The 145 control subjects were contacted by phone by a field worker and were presented the same questions posed to the patients. All 145 patients and 145 control subjects were examined for blood pressure, pulse rate, fasting serum cholesterol, serum triglyceride, blood glucose levels, and urinary protein and sugar.

All parents and siblings who could be reached by phone and were willing to answer our questions were interviewed in the same way as the survivors of myocardial infarction and control subjects. Relatives who were deceased, had no phone, or were otherwise unable or unwilling to cooperate were not excluded from the study, but information on their medical history was obtained either from the index case or from another relative, or by mailing a questionnaire to those without phones. If a person was deceased, every effort was made to obtain a copy of his or her death certificate. Because the ages of the relatives play an important role in the analysis, relatives, either living or dead, whose ages were not precisely known were excluded from the study. Because information on the relatives below age 30 years had not been collected consistently, this age category was excluded also. The family members were not examined.

Description of probands and families: Of the 198 survivors of myocardial infarction, 145 were available for the study. The other 53 (27%) were excluded for the following reasons: 25 refused, 12 had died after discharge from the hospital, in 9 cases the attending physician did not grant permission, 4. were not in the Seattle area by the time of the study, and 3 had acquired another serious disease. To rule out any bias as a result of these exclusions, we compared in detail the hospital records of the 145 patients who did with the 53 patients who did not participate in the study. No evidence of significant differences could be found.

Figure 1 shows the age distributions of the patients and control subjects at the time of interview. The close resemblance of both distributions—caused by the age-matching—is obvious.

Table I gives the number of relatives of the patients and control subjects. Numbers without parentheses refer to relatives whose ages were exactly known and above 29 years; numbers in parentheses include also the relatives below age 30 years or with age unknown who were omitted from further analyses (23 relatives of patients and 33 relatives of control subjects). The mean number of siblings, 2.53 (2.57) and 2.31 (2.40), of patients and control subjects, respectively, did not differ significantly; neither did the sex ratios in both groups of siblings.

Table II shows the number of relatives with and without interviews, the number of dead and living relatives among those without interview, and the number of those with and without death certificate information among the deceased persons. There are no statistically significant differences between relatives of patients and relatives of control subjects in source and completeness of information, nor with respect to the proportion of relatives living or dead.

Figure 2 shows the age distributions of the relatives of both groups of probands. On the average, relatives of patients were 2 years younger than relatives of control subjects (mean age ± standard deviation for relatives of patients [58.99 ± 12.95] and for relatives of control subjects [61.03 ± 13.98]). The difference was statistically significant (Mann-Whitney U test; $p < 0.01$). An even larger difference (4 years) was found for the age at death of those deceased (62.07 ± 13.17 for relatives of

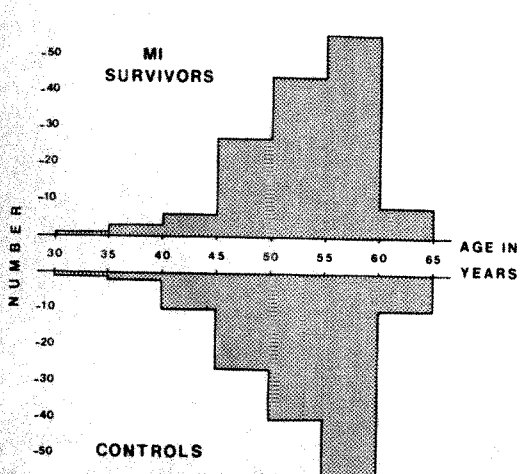

FIGURE 1. Age distributions of patients (survivors of myocardial infarction [MI]) and control subjects.

TABLE I Number of Parents and Siblings of Patients and Control Subjects*

Family Relationship	Number of Relatives of Patients	Number of Relatives of Control Subjects
Father	136 (145)	133 (145)
Mother	136 (145)	137 (145)
Brother	185 (188)	153 (162)
Sister	182 (184)	182 (186)
Total	639 (662)	605 (638)

* Numbers without parentheses refer to relatives whose ages were known exactly and above 29 years; numbers in parentheses also include the relatives below 30 years of age and those with age unknown who were not included in further analysis.

TABLE II Source of Information in Parents and Siblings of Patients and Control Subjects

Source of Information on Relative	Number and Percentage of Relatives of: Patients n	Patients %	Control Subjects n	Control Subjects %
Interview	347	54.3	347	57.4
No interview	292	45.7	258	42.6
Relative deceased	230	36.0	202	33.4

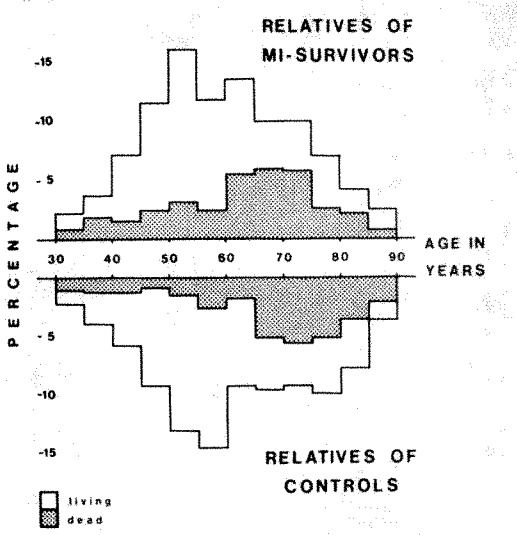

FIGURE 2. Age distributions of first-degree relatives of patients (survivors of myocardial infarction [MI]) and control subjects.

patients and 66.45 ± 14.50 for relatives of control subjects; $p < 0.01$). Presumably this finding was related to frequent and earlier death from coronary heart disease in the relatives of the survivors of myocardial infarction.

The average age of living relatives (57.20 ± 12.51 for relatives of patients and 58.31 ± 12.90 for relatives of control subjects) did not significantly differ for the 2 groups. As expected, the age at death of those deceased was significantly higher than the age of those living, both in relatives of patients and in relatives of control subjects ($p < 0.001$). Because the risk of coronary heart disease increases with age, the analysis of the occurrence of coronary heart disease among the relatives of patients and control subjects has to consider these age differences.

Methods of analysis: Confounding variables such as sex, age, and other risk factors have to be controlled for a meaningful comparison of the prevalence of coronary heart disease in relatives of patients and relatives of control subjects. In the present study this was done in 2 ways.

First, the data were stratified according to the confounding variables. This procedure resulted in a large number of tables with the numbers of relatives of patients and the relatives of control subjects with and without myocardial infarction or coronary heart disease. Within each table, apart from the family history, persons resemble each other with respect to risk factors. For each table the relative risk for developing myocardial infarction or coronary heart disease, depending on the type of family to which a person belongs (patient family or control family), was calculated. The relative risk estimates of these tables were then pooled by the Mantel-Haenzel method and tested for heterogeneity with Woolf's method.[17] This procedure resulted in a *pooled relative risk estimate* for developing myocardial infarction or coronary heart disease.

Stratification of the data results in numerous tables because of the number of risk factors. Many of these tables include few or no persons at all. To reduce the number of tables we used a cumulative risk score (Framingham cardiovascular risk coefficient[18]) instead of separate risk factors. This risk coefficient is obtained by multiplying the value of several risk variables by a coefficient for that variable, summing these products, and adding an intercept. Risk factors included are age, age squared, serum cholesterol, systolic blood pressure, cigarette smoking (yes or no), left ventricular hypertrophy (yes or no), glucose intolerance (yes or no), and cholesterol × age.

Because we desired to control for the effect of risk factors with a significant genetic component, we restricted ourselves to the inclusion of serum cholesterol, blood pressure, glucose tolerance and cholesterol × age in our risk score, using the

TABLE III Prevalence of Coronary Heart Disease Risk Factors Reported by Patients and Control Subjects*

* Because more than 1 risk factor may be reported the total of the columns exceeds the number of probands. † Significance of comparing prevalence of reported risk factors in survivors of myocardial infarction and control subjects. ‡ $0.001 > p$. § $0.05 > p \geq 0.01$. ‖ $0.01 > p \geq 0.001$.

Framingham coefficients for these variables.[18] For instance, the value of our *restricted* risk score for a man aged 45 years with a serum cholesterol level of 200 mg/100 ml, a systolic blood pressure of 150 mm Hg, and no evidence of glucose intolerance will be 0.0258102 × 200 (serum cholesterol) + 0.0156953 × 150 (systolic blood pressure) + 0.6020336 × 0 (glucose tolerance) − 0.0003619 × 200 × 45 (serum cholesterol × age) − 19.770956 (intercept) = −15.51176. Less restricted risk scores, such as scores with inclusion of smoking behavior or smoking behavior and age, were also constructed and used in the analysis.

In the second approach, the *age* at which a relative had a myocardial infarction was analyzed. For this approach the methodology of *life table and survival analysis* was used. In the usual life table method attention is focused on the age at death due to a certain condition. In our analysis we focused

on the age at which myocardial infarction occurred irrespective of death or survival. In the usual life table method "censored" persons are *those who did not die* from the disorder under study until the time of "censoring" (death from other causes, lost to follow-up study, end of study). In our analysis "censored" persons are *those who did not have a myocardial infarction* until the time of "censoring."

The standard life table method allows construction of "survival" curves and comparison of such curves.[19] In this way subsets of the data may be compared 1 by 1 (such as relatives of patients versus relatives of control subjects, males versus females, high risk families versus low risk families). However, a more powerful method is Cox's life table regression model.[20] In this model "censored" survival is considered a function of

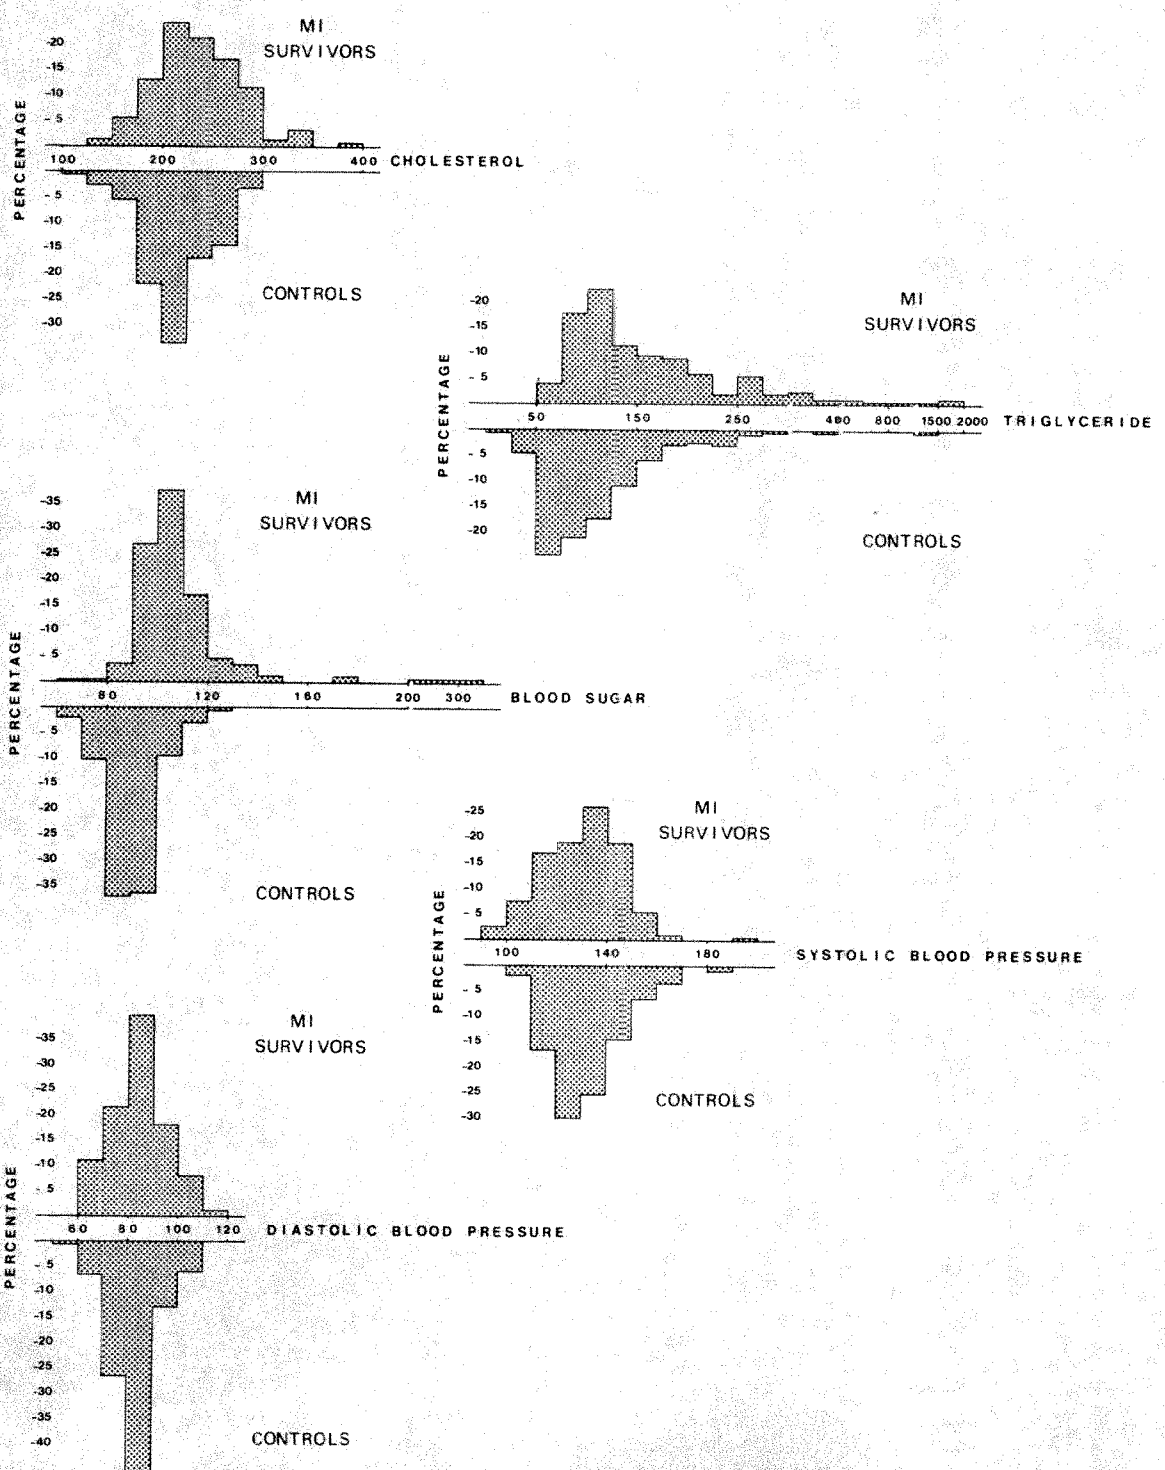

FIGURE 3. Distributions of serum cholesterol, serum triglyceride, fasting blood glucose (mg/100 ml), systolic and diastolic blood pressure (mm Hg) in patients (survivors of myocardial infarction [MI]) and control subjects.

several explanatory variables and unknown regression coefficients multiplied by an arbitrary and unknown function of time. As in classic multiple regression analysis, the model allows simultaneous inferences about the importance of the individual explanatory variables and the unknown regression coefficients.

Throughout this paper p values of 0.05 or greater are regarded as insignificant.

Results

Risk factors in patients and control subjects: Table III shows the reported prevalence of coronary heart disease in patients and control subjects. Figure 3 shows the distributions of serum cholesterol, triglycerides, fasting blood sugar, and systolic and diastolic blood pressure measured in these subjects. The reported prevalence (Table III) of hyperlipidemia, high blood pressure, diabetes mellitus, and cigarette smoking were significantly higher in patients than in control subjects. Correspondingly, the mean serum cholesterol, triglyceride, and blood sugar values in patients were significantly higher than in control subjects (Mann-Whitney U test, $p < 0.001$). However, measured blood pressure, systolic as well as diastolic, was not significantly different in both groups of probands.

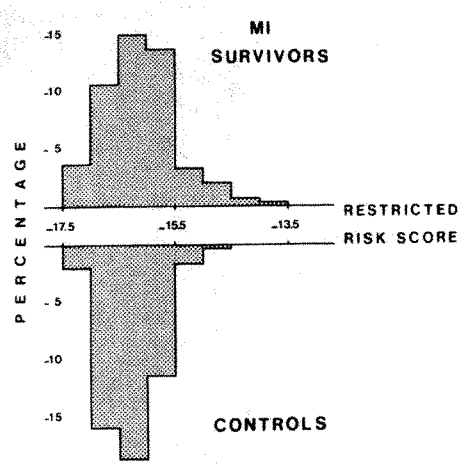

FIGURE 4. Distributions of restricted cumulative risk scores in patients (survivors of myocardial infarction [MI]) and control subjects.

Figure 4 shows the distributions of the restricted cumulative risk scores (see Methods) calculated from serum cholesterol, blood pressure, and glucose tolerance in patients and control subjects. The restricted risk score among patients (-16.10 ± 0.64) was significantly higher than the restricted risk score in control subjects (-16.29 ± 0.44) (Mann-Whitney U test; $p < 0.01$). This also held true when smoking behavior or smoking behavior and age of the proband were included in the computation of the risk score. If the probands were classified according to whether or not they received treatment for hyperlipidemia or hypertension, or both, the risk coefficients were always lowest in control subjects not receiving such treatment. Risk coefficients in these probands generally differed significantly from the risk coefficients in all other groups.

Risk factors in relatives: Table IV compares the reported prevalence of coronary heart disease risk factors in the first-degree relatives of patients and control subjects. Contrary to the findings in the patients and control subjects (Table III), the relatives of patients did not differ significantly from the relatives of control subjects in the reported prevalence of risk factors. However, diabetes and cigarette smoking appear significantly more common among relatives of patients and control subjects with that risk factor than among relatives of those without that risk factor.

A history of high blood lipids or high blood pressure, or both, was not significantly more common among relatives of patients and control subjects with such findings than among relatives of those without such findings. Similarly, high blood lipids and high blood pressure were not significantly more common in relatives of patients and control subjects with serum cholesterol, triglyceride, or systolic or diastolic blood pressure in the upper decile than in relatives of the other patients and control subjects (not shown).

Coronary heart disease in first-degree relatives: Myocardial infarction was reported in 104 (16.3%) of the 639 relatives of patients and in 54 (8.9%) of the 605 relatives of control subjects (Table V). Coronary heart

disease was reported in 131 (20.5%) of the relatives of patients and in 89 (14.7%) of the relatives of control subjects. Coronary heart disease and myocardial infarction therefore were significantly more prevalent in the relatives of patients than in the relatives of control subjects. Table V also shows the percentages of relatives of patients and control subjects with coronary heart disease and myocardial infarction according to their family relationship (parents or siblings), sex (male or female), age category (30 to 52 years, 53 to 66 years, and 67 to 88 years), and level of restricted cumulative risk score (tertiles). Both coronary heart disease and myocardial infarction were always more prevalent among relatives of patients, although the difference was not significant in every subgroup. As expected, the prevalence of coronary heart disease and myocardial infarction was greater in patients than in siblings, greater in men than in women, and increased with advancing age. Unexpectedly, the prevalence of coronary heart disease and myocardial infarction occurring in relatives did not correlate positively with the restricted cumulative risk score in the patient or control subject, but instead showed an opposite trend, at least in the relatives of patients.

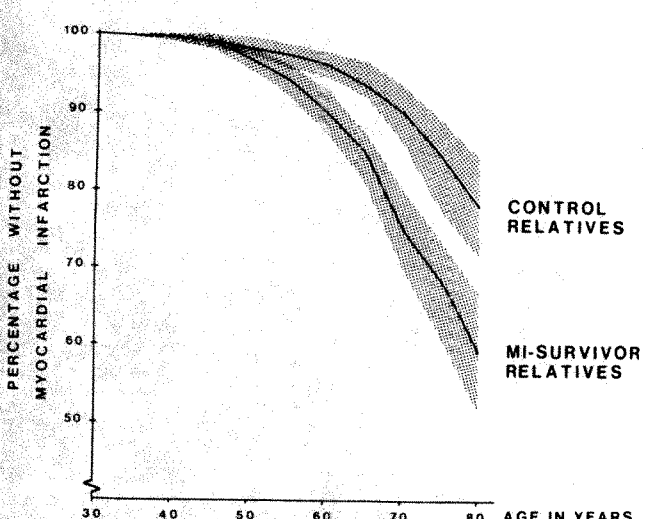

FIGURE 5. Calculated proportions of relatives of patients (survivors of myocardial infarction [MI]) and control subjects without myocardial infarction at reaching ages 30 through 80 years (means with 95% confidence intervals). Calculation according to standard life table method.[19]

Figure 5 shows the calculated proportions of relatives without myocardial infarction on reaching ages 30 through 80 years (standard life table method[19]). When the precise age at their first myocardial infarction was not known (in 58.7% of the relatives of patients and 42.6% of the relatives of control subjects), we used the age at death (77 patients) or "censoring" for other reasons (7 patients). This may have caused some shifting of both curves toward later myocardial infarctions, presumably more so in the patient families (because of the larger number of persons whose age at first myocardial infarction was not known exactly) than in control families. Therefore, the already clear-cut distinction between relatives of patients and relatives of control subjects, shown in Figure 5, may underestimate the real difference.

Relative risk analysis: Data stratification according to type of family (patient or control subject), level of the restricted cumulative risk score in patients or control subjects, age and sex of the relatives, and presence or absence of myocardial infarction than coronary heart disease in these relatives is shown in Table VI. The

* See Methods.

relative risk analysis of these data (Table VII) shows that first-degree relatives of patients have somewhat over twice the risk of having myocardial infarction than first-degree relatives of control subjects, and about 1.7 times the risk of having coronary heart disease. Separate analyses of relatives of patients and control subjects with low risk factors (lipids, blood pressure, and blood sugar) or with low restricted cumulative risk scores show the same results as do analyses with subcategorization of the data according to presence or absence of treatment (either drug or diet) in the patients and control subjects. Similarly, using quartiles instead of tertiles, combining tables with zero observations in 1 or 2 boxes with other tables in several ways, and including smoking behavior or smoking behavior and age in the restricted cumulative risk score all give the same result: myocardial infarction is twice as common in the relatives of patients, irrespective of risk factors in the probands.

Cox's life table regression analysis: Table VIII shows the result of a typical run of the Cox's life table regression analysis. A large number of such analyses have been done, differing among each other in the number and nature of independent variables (risk factors) that were included. Consistent features were the significant positive effect of belonging to a patient family and of male sex, and the absence of any significant effect of the restricted cumulative risk score in patients or control subjects. The presence of drug treatment in patient or control subjects seemed to have some predictive value. Assignment of all the patients and control subjects with drug treatment to the upper tertile of the restricted cumulative risk score did not

TABLE VII Results of the Relative Risk Analysis.*

Disease	Pooled Relative Risk Estimate (R)	Test on R = 1			Test on Homogeneity		
		Chi-Square	df	p	Chi-Square	df	p
Myocardial infarction	2.14	16.463	1	<0.001	19.822	17	0.283
Coronary heart disease	1.71	10.607	1	0.001	26.826	17	0.061

* Data of 18 tables, each containing numbers of relatives of patients and control subjects with and without the disease under study, and differing among each other in risk levels (see Table VI) were pooled according to the Mantel-Haenzel method to obtain a pooled relative risk estimate. Pooling seems justified because no significant heterogeneity was apparent among the 18 tables. The pooled relative risk estimates obtained differ significantly from the null hypothesis of equal risk (R = 1).

TABLE VIII Results of Cox's Life Table Regression Analysis*

Risk Factor	Coefficient	SE	p	Significance of Regression (p)
Type of family†	0.685	0.176	<0.001	<0.001
Sex‡	0.950	0.171	<0.001	. . .
Drug treatment§	0.445	0.184	0.016	. . .
RRS	0.040	0.098	0.682	. . .

* As shown, the age at which myocardial infarction develops in relatives depends significantly on the set of risk factors analyzed. However only 3 of the 4 risk factors contribute significantly. The estimated regression coefficients with the standard error of the estimate are also shown. † Type of family (0 = control family; 1 = case family). ‡ Sex of relative (0 = female; 1 = male). § Drug treatment: presence (= 1) or absence (= 0) of drug treatment in patient or control subject. RRS = restricted cumulative risk score of patient or control subject (0 = lowest tertile; 1 = middle tertile; and 2 = highest tertile); SE = standard error.

improve the predictive value of that score. Neither did inclusion of smoking or smoking and age into the risk score. Other analyses were done on those without restricted risk score but with actual serum cholesterol, blood sugar, and systolic blood pressure as independent variables, as well as analyses of subsets of the data such as on relatives of patients and control subjects with and without drug or drug or diet treatment. The same picture always emerged: The *age* at which relatives had their first myocardial infarction did not so much depend on the known (genetic) risk factors in the proband as on other unknown factors distinguishing patient from control families.

Discussion

The question of how much of the familial aggregation of coronary heart disease is explained by the familial aggregation of hitherto-discovered risk factors has intrigued researchers for some time. In our present study we could confirm the higher risk level of patients compared with control subjects, but we were unable to discover more than faint indications of a correlation between the risk level and a family history of coronary heart disease.

The data presented herein are subject to certain considerations. First, when dealing with a retrospective study the possibility of misclassification with respect to risk factors exists because of past intervention. For instance, in this study blood pressure levels were similar for patients and control subjects. However, this intervention bias was taken into account by distinguishing between patients and control subjects with and without treatment. Only a minor effect on the data was apparent. Second, differential reporting of coronary events by patients and control subjects has often been suggested to be a source of bias in case-control studies. We therefore insisted, as much as possible, on interviewing the family members themselves or on inspecting death certificates. Because we failed to achieve this in 15% of patient relatives and 13% of control relatives, differential reporting cannot be ruled out completely, but more than a small effect seems unlikely. Third, blood bank donors may not be an ideal control group because they may be more healthy or health-conscious than the general population. If this were so, it would have enlarged the difference in risk level of patients and control subjects and, presumably, would have resulted in too large a role for risk factors compared with family history. Because it appeared that in our study risk factors did not predict coronary heart disease in relatives, this possible bias can be ignored.

According to our present study the clustering of coronary heart disease in families cannot be explained by the familial aggregation of hyperlipidemia, hypertension, diabetes, or smoking. Epstein[21] in 1967 speculated that the known degree of familial resemblance of serum cholesterol and blood pressure were insufficient to account for the familial clustering of coronary heart disease. Since then several studies have been devoted to the possible correlations between risk factors and familial occurrence of coronary heart disease. These studies differ greatly in methodology and study design. Starting from data obtained in prospective population studies, at least 3 approaches have been described. In the first approach[22,23] the family history of persons with low risk levels was compared with the family history of those with high risk levels. The second approach compared the risk levels of persons with a family history of coronary heart disease and the risk levels of those without such a family history.[24–27] In the third approach the study population was followed up for some time, and the predictive strength of risk factor levels and family history in relation to the incidence of new cases of coronary heart disease was studied.[28–31]

Case-control studies on the correlations between familial coronary heart disease and risk factors can be divided into 2 types: those starting from a series of patients who underwent coronary angiography, and those starting from a series of patients with clinical end points such as myocardial infarction or angina pectoris. In the first type of studies the study group is composed of patients with significant coronary obstruction whereas the control subjects are those who also underwent coronary angiography because of symptoms but did not show significant coronary obstruction.[32–35]

Although the attraction of these studies lies in the precise anatomic definition of coronary heart disease, these results are not completely applicable to clinical end points such as myocardial infarction. Dimsdale et al.[36] followed up a cohort of 189 men for 1 year after performance of angiography and determination of cardiovascular risk factors to ascertain which risk factors or clinical and laboratory findings could aid in predicting which patients would have a substantial cardiac morbid event later. Stepwise discriminant analysis revealed that a positive family history in first-degree relatives ranked third among all risk factors, right after the severity of angina and a history of previous myocardial infarction.

Apart from our present study, 2 case-control studies[9,37] starting from patients with clinical end-point manifestation of coronary heart disease have been described. These 2 studies reach completely different conclusions. Rissanen and Nikkilä[37] concluded that most of the familial aggregation of coronary heart disease is mediated by familial aggregation of hyperlipidemia or hypertension. This finding differs sharply from the conclusions of Nora et al.,[9] who incorporated family history along with other factors in their risk index. The Michigan Heart Association earlier also included family history as well as other risk factors in a risk index.[38]

With the exception of the report of Rissanen and Nikkilä,[37] earlier studies tend to be in accord with the findings presented here. It is possible that Rissanen and Nikkilä's findings are somehow specific for the Finnish population with its higher frequency of coronary risk factors.[39,40]

If other familial risk factors are postulated, how do they fit in the coronary risk profile as compared with

already known familial risk factors? The presently known risk factors are not mutually exclusive but exert their effect in an additive way.[41] The same may apply to the postulated unknown factors, but the present study does not solve this problem, nor does it establish to what extent the unknown familial risk factors have a genetic basis. Familial aggregation can be caused by genetic factors or by environmental factors common to family members, or by interaction of genetic susceptibility with specific environmental factors. For instance, the major risk factors may have a stronger impact on those with a familial predisposition. Future work will need to identify the specific familial factors that lead to familial aggregation of coronary heart disease. Unfortunately, at the time the study was designed, the role of high-density lipoprotein cholesterol was not recognized. Lipoprotein characteristics should be taken into account in future studies of familial clustering of coronary heart disease.[31] Other possible risk factors may be found in Hopkins and William's survey[42] of 246 suggested coronary risk factors.

Acknowledgment

We acknowledge the help of doctors and administrators of Group Health Hospital, Swedish Hospital, Virginia Mason Hospital, and Doctor's Hospital, Seattle, Washington, for case finding and of Dennis Donohue, MD, then Director of Puget Sound Blood Center, for finding control persons. Serum cholesterol and triglyceride determinations were done in the Northwest Lipid Research Center (John D. Brunzell, MD, William Hazzard, MD, and John J. Albers, PhD), and blood glucose determination in the Veterans Administration Hospital Laboratory, Seattle, Washington. Jurg Ott, PhD, suggested the use of the pooled relative risk estimate methodology and supervised this and other statistical applications. The Cox's life table regression computer program was provided by John Holt, PhD, from Guelph University, Ontario, Canada. Interviews, blood drawing, and blood pressure measurements were done by Ellen Campbell, Mary Jo Levinski, Susan Rasmussen, and Mary Sheriff. Noriko Isono and Cindy Sheriff provided logistical support. Programming and data treatment were handled by Robert W. Cottingham. Pieter J. Offringa, Mentje Dijkstra, Sylvia Groenewegen, and Sylvia Waggoner helped in preparing the manuscript.

Assessment of Vasodilator Therapy in Patients With Severe Congestive Heart Failure: Limitations of Measurements of Left Ventricular Ejection Fraction and Volumes

BRIAN G. FIRTH, MD, DPhil, GREGORY J. DEHMER, MD, ROY V. MARKHAM, Jr., MD, JAMES T. WILLERSON, MD, and L. DAVID HILLIS, MD

Although noninvasive techniques are often used to assess the effect of vasodilator therapy in patients with congestive heart failure, it is unknown whether changes in noninvasively determined left ventricular ejection fraction, volume, or dimension reliably reflect alterations in intracardiac pressure and flow. Accordingly, we compared the acute effect of sodium nitroprusside on left ventricular volume and ejection fraction (determined scintigraphically) with its effect on intracardiac pressure and forward cardiac index (determined by thermodilution) in 12 patients with severe, chronic congestive heart failure and a markedly dilated left ventricle. Nitroprusside (infused at 1.3 ± 1.1 [mean ± standard deviation] μg/kg/min) caused a decrease in mean systemic arterial, mean pulmonary arterial, and mean pulmonary capillary wedge pressure as well as a concomitant increase in forward cardiac index. Simultaneously, left ventricular end-diastolic and end-systolic volume indexes decreased, but the scintigraphically determined cardiac index did not change significantly. Left ventricular ejection fraction averaged 0.19 ± 0.05 before nitroprusside administration and increased by less than 0.05 units in response to nitroprusside in 11 of 12 patients. The only significant correlation between scintigraphically and invasively determined variables was that between the percent change in end-diastolic volume index and the percent change in pulmonary capillary wedge pressure (r = 0.68, p = 0.01). Although nitroprusside produced changes in scintigraphically determined left ventricular ejection fraction, end-systolic volume index, and cardiac index, these alterations bore no predictable relation to changes in intracardiac pressure, forward cardiac index, or vascular resistance. Furthermore, nitroprusside produced a considerably greater percent change in the invasively measured variables than in the scintigraphically determined ones.

Vasodilator therapy is widely used in severe congestive heart failure,[1-6] and the effects of sodium nitroprusside and other vasodilators are well characterized with invasive techniques.[7-11] More recently, several investigators have used echocardiography[12-15] or radionuclide ventriculography[15-21] to assess the efficacy of several vasodilators in these patients. Although these investigators assume that such a noninvasive assessment is reliable and sensitive, others[22,23] suggest that these noninvasive techniques may not reflect the hemodynamic changes that occur in response to therapy. Therefore, in the present study of patients with severe congestive heart failure, we simultaneously assessed the acute effect of sodium nitroprusside on intracardiac pressure, forward cardiac output (by thermodilution), and systemic and pulmonary vascular resistance as well as on radionuclide-determined left ventricular volume, ejection fraction, and cardiac index.

In so doing, we attempted to answer the following questions: In patients with severe congestive heart failure and a dilated left ventricle given nitroprusside: (1) Do alterations in scintigraphically determined left ventricular volume, ejection fraction, and cardiac index correlate with simultaneously measured changes in in-

tracardiac pressure, forward cardiac index, or vascular resistances? (2) Which scintigraphically determined variable is the most reliable predictor of alterations in intracardiac pressure or forward cardiac index? (3) What is the relative magnitude of changes produced by nitroprusside in scintigraphically and invasively determined variables?

Methods

Patients

After informed consent was obtained, 12 patients (11 men and 1 woman, mean age 49 years) with New York Heart Association class III or IV congestive heart failure had cardiac catheterization according to the protocol detailed herein. All patients were in sinus rhythm, on maintenance digitalis and diuretics, and in some cases on antiarrhythmic agents; no patient was receiving other vasodilator agents. Most patients were thought to have idiopathic congestive cardiomyopathy, although some had a history of ethanol excess. Selective coronary angiography was performed in 10 patients; 2 had evidence of significant coronary artery disease (greater than 70% luminal diameter narrowing) involving 1 vessel in 1 patient and 2 vessels in the other. Radiographic (angiographic) evidence of mitral regurgitation was present in 11 patients, ranging from 1+ to 4+.[24] No patient had evidence of valvular stenosis or an intracardiac shunt.

Study Protocol

Cardiac catheterization: Cardiac catheterization was performed through the percutaneous Seldinger approach or brachial cutdown or both. Right heart catheterization was performed with a flow-directed, balloon-tipped thermodilution catheter (Electronics for Medicine thermodilution

catheter 62 00 37) advanced to the pulmonary artery under fluoroscopic control. At baseline, multigated blood pool imaging was performed for 6 minutes, during which intracardiac pressures were recorded in duplicate, and forward cardiac output was measured by the thermodilution technique.[25] The average of 3 to 5 thermodilution measurements of forward cardiac output was used for the final computations. The variability of thermodilution measurements in our laboratory is ±4%.

After baseline measurements, intravenous sodium nitroprusside was infused at 0.25 μg/kg/min. A steady infusion was continued for 10 minutes, at which time pressure measurements, multigated blood pool imaging, and thermodilution cardiac output measurements were repeated. Subsequently, scintigraphic and hemodynamic measurements were accomplished after a 10 minute nitroprusside infusion at 0.50, 1.0, 2.0, and 4.0 μg/kg/min. The stepwise nitroprusside infusion was continued until pulmonary capillary wedge pressure decreased 35% or to an absolute level of 15 mm Hg. The maximal tolerated dose ranged from 0.25 to 4.0 μg/kg/min (mean 1.33). After nitroprusside infusion, left ventricular contrast angiography was performed in all patients.

Radionuclide ventriculography: Red blood cells were labeled with 30 mCi of technetium-99m sodium pertechnetate using a technique combining features of both in vitro and in vivo labeling.[26] Scintigraphic data collection was performed with a portable gamma scintillation camera (Series Sigma 420, Ohio Nuclear, Solon, Ohio), as previously described.[26–30] Left ventricular volume and ejection fraction were estimated by a totally nongeometric technique developed and validated in our laboratory.[26–28]

All volumes were normalized for body surface area. The interobserver and intraobserver variability of these volume measurements in our laboratory is 7.5 and 6%, respectively, and the reproducibility of these measurements over time has been substantiated.[29]

Statistical analysis: The mean ± standard deviation was determined for each variable at baseline and at peak nitroprusside infusion (Tables I and II). A paired *t* test was performed to compare changes in each variable between baseline and peak nitroprusside infusion. Nonparametric methods were used whenever unequal variances among groups were present.[31] A p value less than 0.05 was considered significant. Linear regression analysis was performed to compare the absolute change in each invasively determined variable with the absolute change in each variable determined by multigated blood pool scan (Table III) in response to nitroprusside. Similarly, linear regression analysis was performed to compare the percent change in each invasively measured variable with the percent change in each variable measured by multigated blood pool scan (Table IV) in response to nitroprusside. When more than 2 variables appeared interrelated, multivariate regression analysis was performed.

Results

Invasive hemodynamic measurements: The heart rate and invasively determined hemodynamic variables for each patient are shown in Table I. The heart rate averaged 95 ± 21 beats/min at rest and 92 ± 18 beats/min during peak nitroprusside infusion (difference not significant [NS]). The forward cardiac index (by thermodilution) increased from 2.06 ± 0.41 liter/min/m^2 at rest to 2.91 ± 0.62 during peak nitroprusside infusion ($p < 0.005$). Mean pulmonary capillary wedge pressure decreased from 26 ± 6 mm Hg before to 14 ± 5 at maximal nitroprusside infusion ($p < 0.001$), while mean pulmonary arterial pressure decreased from 38 ± 10 mm Hg to 25 ± 7 ($p < 0.001$). Similarly, mean femoral arterial pressure decreased from 89 ± 8 mm Hg to 75 ± 9 ($p < 0.005$). Total pulmonary vascular resistance averaged

Abbreviations as in Table III.

861 ± 406 dynes·s·cm^{-5} and decreased to 385 ± 124 during maximal nitroprusside infusion ($p < 0.001$). Likewise, total systemic vascular resistance decreased in response to nitroprusside from 1,975 ± 625 dynes·s·cm^{-5} to 1,154 ± 202 ($p < 0.001$).

Multigated blood pool imaging measurements: The scintigraphically determined left ventricular ejection fraction, volumes, and cardiac index for individual patients are shown in Table II. Left ventricular ejection fraction averaged 0.19 ± 0.05 at baseline and increased slightly, but significantly, to 0.23 ± 0.05 during peak nitroprusside infusion ($p < 0.005$). However, the absolute increase in ejection fraction was greater than 0.05 units (the accepted limit of observer error)[32] in only 1 patient. The left ventricular end-diastolic volume index decreased in response to nitroprusside from 185 ± 61 to 152 ± 55 ml/m^2 ($p < 0.001$), whereas the end-systolic volume index decreased from 150 ± 51 ml/m^2 at baseline to 120 ± 45 during maximal nitroprusside infusion ($p < 0.001$). Cardiac index by multigated blood pool scan did not change significantly in response to nitroprusside (3.13 ± 1.02 liters/min/m^2 at baseline, 2.89 ± 0.99 during peak nitroprusside; NS).

Invasive versus multigated blood pool data: The relation between the absolute change in each invasively determined variable and each measurement determined by multigated blood pool imaging for individual patients is shown in Table III. Only 1 group of variables approached a significant correlation, namely, the absolute change in mean pulmonary capillary wedge pressure and the absolute change in cardiac index determined by multigated blood pool scan ($r = 0.57$, $p = 0.05$). However, because 24 such comparisons were performed, this chance finding might be anticipated. The spurious nature of this apparent correlation is further emphasized by the fact that although pulmonary capillary wedge pressure decreased markedly, cardiac index by gated blood pool scan did not change significantly. Thus, no correlation appears to exist between the absolute change in any of the invasively determined measurements and those determined by multigated blood pool scan.

The relation between the percent change in invasive measurements and that in radionuclide measurements is shown in Table IV. There was a significant correlation between the percent change in pulmonary capillary wedge pressure and that in left ventricular end-diastolic volume index ($r = 0.68$, $p = 0.01$) as well as the percent change in left ventricular end-systolic volume index ($r = 0.60$, $p < 0.05$). However, the percent change in end-diastolic volume and that in end-systolic volume are themselves highly correlated ($r = 0.89$, $p < 0.001$). Trivariate regression analysis, comparing the percent change in pulmonary capillary wedge pressure (PCW) and end-diastolic (EDVI) and end-systolic (ESVI) volume indexes (PCW = 31.9 − 0.067 [ESVI] + 0.8088 [EDVI]), suggests that the primary correlation is between the percent change in pulmonary capillary wedge pressure and the percent change in end-diastolic volume index. However, the statistical significance of even this correlation is in question when the Bonferroni adjustment for multiple comparisons is applied.[31] The relation between the percent change in pulmonary capillary wedge pressure and end-diastolic volume index as well as the 95% confidence limits is shown in Figure 1. There was no significant relation between the percent change in any other invasively measured and scintigraphically determined variable.

Discussion

In patients with congestive heart failure, vasodilator therapy is considered effective when it causes an increase in forward cardiac output or a decrease in pulmonary vascular congestion, or both, without associated systemic arterial hypotension. Although changes in noninvasively determined left ventricular volume, cardiac output, and ejection fraction are often used to evaluate the response to vasodilator therapy,[12–21] the exact relation between changes in these variables and alterations in invasively determined ones in patients with severe congestive heart failure has not been characterized. In particular, it is not clear whether changes in pulmonary capillary wedge pressure, pulmonary arterial pressure, or forward cardiac output are related to changes in any of the variables measured by radionuclide ventriculography. Therefore, the present study was performed to assess the relation between changes in variables measured by radionuclide ventriculography and those determined invasively in patients with severe congestive heart failure given sodium nitroprusside.

Changes in radionuclide and invasive measurements: In the present study, nitroprusside produced a hemodynamic response similar to that reported previously[7–11]: forward cardiac index increased, whereas mean pulmonary capillary wedge, mean pulmonary arterial, and mean femoral arterial pressures decreased. Total pulmonary vascular and systemic vascular resistances decreased, whereas heart rate did not change significantly (Table I). Simultaneously, mean left ventricular ejection fraction increased from 0.19 to 0.23, an observation that would seem to lend credence to the use of this variable in assessing the efficacy of vasodilator therapy.[16–19] Although this change is statistically significant, its clinical relevance is questionable because the absolute change is less than 0.05 units (the accepted variability of absolute ejection fraction for repetitive studies in abnormal patients)[32] in 11 of the 12 patients. Finally, nitroprusside caused a progressive decrease in both end-diastolic and end-systolic volume indexes but no change in total cardiac index as measured by radionuclide ventriculography.

Changes in invasive versus noninvasive measurements: The absolute changes in forward cardiac index, mean pulmonary capillary wedge, pulmonary arterial, and femoral arterial pressures, and total pulmonary and systemic vascular resistances produced by nitroprusside bore no relation to the absolute changes in left ventricular ejection fraction, end-diastolic volume index, end-systolic volume index, and cardiac index by radionuclide ventriculography (Table III). When changes in the invasively and noninvasively determined variables were expressed as percentages, the only sig-

nificant correlation was between the percent change in left ventricular end-diastolic volume index and the percent change in mean pulmonary capillary wedge pressure (Table IV). Although the correlation coefficient for this relationship is 0.68, the 95% confidence limits are wide (Fig. 1). In addition, the large negative intercept implies that a reduction in pulmonary capillary wedge pressure of more than 30% might occur without a change in end-diastolic volume index. None of the radionuclide measurements was predictive of the observed increase in forward cardiac output.

The observed disparity between the changes in radionuclide and invasive measurements suggests 1 of 2 possibilities. First, the radionuclide technique may be intrinsically invalid in patients with severe congestive heart failure. We cannot exclude this possibility because we have not compared ventricular volumes measured by radionuclide and contrast ventriculography in patients with a low ejection fraction. However, previous investigators[33] showed an excellent correlation between radionuclide and contrast angiographic measurements of left ventricular ejection fraction, even in those with severe left ventricular dysfunction and ejection fraction less than 0.30. Furthermore, we[30] previously demonstrated that radionuclide and contrast angiographic measurements of left ventricular volumes correlate closely, even in patients with a markedly dilated left ventricle (due to aortic regurgitation). In light of the aforementioned data, it seems reasonable to assume that both left ventricular ejection fraction and absolute volumes can by measured accurately using a count-based, nongeometric radionuclide ventriculographic technique in these patients.

In patients with severe congestive heart failure, the validation of the radionuclide-determined stroke volume by another technique (such as thermodilution stroke volume measurements) is problematic. Because mitral regurgitation is an almost invariable accompaniment of severe congestive heart failure, total cardiac output (as measured by radionuclide ventriculography) exceeds forward cardiac output. Thus, in these patients the radionuclide measurement of cardiac output cannot be validated by comparing it with a measurement of forward cardiac output. In the present study, 11 of the 12 patients had angiographic evidence of mitral regurgitation (1 to 4+). As a result, the lack of correlation between radionuclide-determined (total) and thermodilution-determined (net forward) cardiac index in this study is not unexpected.

Second, it is conceivable that both the radionuclide and the invasive techniques are measuring changes accurately but that the changes measured are not linearly related to one another. A major reason for the poor correlation between changes in left ventricular volume and changes in filling pressure may be that nitroprusside alters left ventricular compliance.[9] In the present study, left ventricular end-diastolic and end-systolic volume indexes decreased in each patient, but left ventricular ejection fraction behaved less predictably. This finding is particularly noteworthy because changes in left ventricular ejection fraction by radionuclide ventriculography have been widely used[15–21] to assess the effects of vasodilator therapy. The disparity between the changes in left ventricular ejection fraction and the changes in invasive measurements can be explained in several ways: (1) Changes in ejection fraction may be measured accurately but fall within the limits of resolution of the system used for their detection. In 11 of 12 patients the detected change was less than the accepted limit of observer error (0.05 units). (2) Even if the radionuclide technique is valid, the detection of small changes in a large ventricle is likely to be less accurate than the detection of the same magnitude of change in a small ventricle. (3) The differential effects of nitroprusside on preload and afterload in patients with various degrees of mitral regurgitation might produce various effects on left ventricular ejection fraction. Conceptually, reduction of the effective mitral orifice size[34,35] and removal of a low impedance outlet (by predominant preload reduction) might result in a decrease in left ventricular ejection fraction; alternatively, a predominant afterload reduction might result in an increase in ejection fraction. Although our suggestion that left ventricular ejection fraction might decrease because of a predominant preload effect is purely hypothetical, a reduction in the left ventricular ejection fraction after mitral valve replacement for mitral regurgitation is well documented.[36] Each of these 3 factors may play some role in rendering the left ventricular ejection fraction of limited value in assessing the effect of vasodilators in the individual patient with severe congestive heart failure.

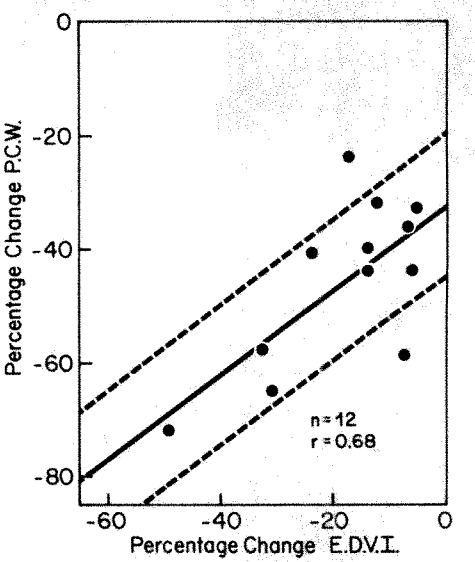

FIGURE 1. The percent change in pulmonary capillary wedge pressure (PCW) versus the percent change in left ventricular end-diastolic volume index (EDVI) in response to nitroprusside infusion. The 95% confidence limits of the intercept are shown. Although the correlation between these 2 variables is acceptable, the large negative intercept implies that a reduction in pulmonary capillary wedge pressure of more than 30% might occur without a change in end-diastolic volume index.

Two points about the present study deserve emphasis. First, it attempts to explore the effects of *acute* vasodilator therapy (with sodium nitroprusside) on both

hemodynamic and scintigraphic variables in a well-controlled setting free from motion artifact (such as might occur during exercise). Second, the patients comprising this study had severe left ventricular dysfunction; in addition, most had mitral regurgitation due to left ventricular dilatation. It is conceivable that patients with less severe left ventricular dysfunction as well as those without associated mitral regurgitation might respond differently to nitroprusside. However, mitral regurgitation due to ventricular dysfunction is an almost invariable finding in precisely the patients in whom nitroprusside and other vasodilators are most likely to be used.

Clinical implications: In patients with severe congestive heart failure and a greatly enlarged left ventricle, marked hemodynamic changes may occur without detectable changes in left ventricular ejection fraction. Although acute nitroprusside infusion causes a reduction in both left ventricular end-diastolic and end-systolic volume (measured by radionuclide ventriculography), these changes cannot readily be used to predict alterations in pulmonary capillary wedge pressure or forward cardiac output.

Effects of Acute and Chronic Minoxidil Administration on Rest and Exercise Hemodynamics and Clinical Status In Patients With Severe, Chronic Heart Failure

MARK NATHAN, MD, STANLEY A. RUBIN, MD, DEIRDRE SIEMIENCZUK, RN and H. J. C. SWAN, MD

The effects of acute and chronic oral administration of the vasodilator minoxidil on hemodynamics, oxygen consumption, exercise performance, and clinical status were investigated in 10 patients with severe, chronic heart failure refractory to digitalis and diuretic therapy. The cardiac index was 1.99 ± 0.38 liters/min/m^2 at rest and 2.88 ± 0.79 at symptom-limited maximal exercise on conventional therapy, compared with 2.64 ± 0.33 liters/min/m^2 at rest and 3.55 ± 0.84 at maximal exercise after short-term minoxidil administration ($p < 0.02$, control versus minoxidil at both rest and exercise). Stroke volume was increased after minoxidil treatment, without significant effect on heart rate. Systemic vascular resistance was decreased by minoxidil from 2,050 ± 722 to 1,325 ± 374 dynes·s/cm^{-5} at rest and from 1,500 ± 830 to 1,206 ± 589 dynes·s/cm^{-5} at maximal exercise ($p = 0.01$, control versus minoxidil). No significant effect was observed on left ventricular filling, right atrial, or mean pulmonary arterial pressure, but pulmonary vascular resistance decreased both at rest and on exercise ($p < 0.05$). Maximal exercise oxygen consumption increased from 8.9 ± 3.2 ml/kg/min on conventional therapy to 10.5 ± 2.4 on minoxidil therapy ($p < 0.03$), median maximal exercise work load increased from 25 to 50 W and median exercise duration increased from 6.0 to 9.0 minutes. On chronic minoxidil administration all 5 patients who completed a scheduled 6 week follow-up showed symptomatic improvement. However, worsening edema developed in all patients, requiring increased diuretic dosage and close supervision. Symptoms of ischemic heart disease worsened in 2 of 10 patients. We tentatively conclude that minoxidil may be a useful vasoactive agent in the pharmacologic therapy of severe chronic heart failure.

Administration of vasoactive drugs to patients with severe chronic congestive heart failure refractory to conventional therapy with digitalis and diuretics has been shown to result in salutary hemodynamic and clinical effects.[1,2] However, there is no consistent evidence that short-term administration of vasodilator drugs, including nitrates,[3] prazosin,[4,5] hydralazine,[6,7] and combination therapy[8,9] improve maximal oxygen consumption or exercise performance. There is also a scarcity of data from controlled clinical trials suggesting any long-term benefit from vasodilators in heart failure.

From the Division of Cardiology, Department of Medicine, Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, California. Manuscript received November 9, 1981; revised manuscript received March 30, 1982, accepted May 26, 1982.

Previous preliminary reports have demonstrated beneficial effects of the direct-acting arteriolar vasodilator minoxidil in patients with chronic congestive heart failure at rest.[10–12] The effects of short-term minoxidil administration on exercise hemodynamics or performance and the effects of chronic minoxidil administration on clinical outcome have not previously been reported in patients with severe chronic heart failure. The purpose of this study was to investigate the hemodynamic and clinical effects of short-term minoxidil therapy on the exercise performance of patients with severe chronic heart failure.

Methods

Study population: The study population consisted of 10 patients, 7 men and 3 women, with a mean age of 65 years (range 44 to 77). The cause of chronic heart failure was ischemic heart disease in 8 patients and idiopathic cardiomyopathy in 2. Six patients had previous aortocoronary bypass grafting, and of this group 2 had mitral valve replacement

and 1 had aortic valve replacement. Prosthetic valve function was normal in these 3 patients. Symptoms of heart failure were present for a median duration of 28 months (range 1 to 84) before entry into the study. All patients gave a history of slowly worsening symptoms before entry into the study despite empirical optimization of therapy with digitalis and diuretics. No patient had acute pulmonary edema or myocardial infarction within the month before admission. At the time of admission, all patients were in New York Heart Association (NYHA) functional class III or IV.[13] The mean digoxin dose was 0.18 mg/day and the mean furosemide dose was 118 mg/day (range 40 to 160). No patient had current symptoms of angina pectoris. Four patients had previously received a trial of vasodilator therapy (1 patient prazosin and 3 patients hydralazine) but all vasoactive medication was withdrawn at least 48 hours before entry into the study. No patient had clinically severe mitral regurgitation, but 3 patients had clinical evidence of tricuspid regurgitation from secondary right heart failure. The resting left ventricular ejection fraction measured by the gated equilibrium blood pool technique[14] was severely depressed in all patients, with a mean value of 0.20 ± 0.07.

All patients were hospitalized in the coronary care unit a minimum of 48 hours before study initiation. During this time dietary sodium intake was restricted, and stable doses of digitalis and diuretics were administered. This protocol was approved by the Human Subjects committee of this institution. Signed, informed consent was obtained from all patients.

Hemodynamic measurements and oxygen consumption: A Swan-Ganz balloon flotation thermodilution catheter was inserted percutaneously from the internal jugular vein in all patients. Cardiac output (liters/minute) was measured in duplicate by thermodilution in 8 patients and by the Fick principle in 2 patients. The correlation between these 2 techniques in our laboratory is 0.91 at rest and 0.92 at exercise, and is not affected by the presence or absence of tricuspid regurgitation (unpublished observations). Left ventricular filling pressure (LVFP, mm Hg) was estimated by the mean pulmonary capillary wedge pressure or pulmonary arterial diastolic pressure, the method remaining constant for a given patient. Blood pressure (mm Hg) was measured using an indwelling radial artery cannula. Heart rate (beats/minute) was recorded from the electrocardiogram at the time of cardiac output determination. Systemic vascular resistance (SVR, dynes·s/cm^{-5}) was calculated as SVR = $[(\overline{MAP} - \overline{RA})/CO] \times 80$, where MAP = mean arterial pressure, $\overline{RA}$ = mean right atrial pressure, and CO = cardiac output. Pulmonary vascular resistance (PVR) was calculated as PVR = $[(\overline{PA} - LVFP)/CO] \times 80$, where $\overline{PA}$ = mean pulmonary arterial pressure.

Oxygen saturation (fraction) and hemoglobin concentration (g/dl) were measured spectrophotometrically (Instrumentation Laboratories #282 Co-oximeter). Oxygen content (ml O_2/dl) was calculated as oxygen saturation fraction × hemoglobin concentration ×1.34. Arteriovenous oxygen content difference (A-VO_2, ml O_2/dl) was calculated as $C_a - C_v$, where C_a = arterial oxygen content and C_v = mixed venous (pulmonary arterial) oxygen content.

Oxygen consumption ($\dot{V}O_2$, ml O_2/kg/min, standard temperature and pressure, dry) was measured by analysis of expired gas. Timed collections of expired gas were made through a low resistance 2-way valve (modified Otis-McKerrow, Collins Corporation, Cambridge, Massachusetts) into latex meteorologic balloons. Three minute gas collections were made at rest and 1 to 2 minute collections made at peak exercise. Gas analysis was performed soon after collection using a mass spectrometer (Perkin-Elmer, MGA 1100, Pomona, California) for fractional gas concentration determination and a gasometer for volume determination.

Exercise protocol: Sequential measurements at rest and during exercise were made in the postabsorptive state at about the same time of day. A trial exercise period was performed the day before formal entry into the study to familiarize the patient with the procedure. The patient sat upright on the cycle ergometer (Monark), and his feet were secured to the pedals. After at least 10 minutes of equilibration, resting measurements were recorded. Progressive cycle exercise was performed to symptom-limited maximum using successive workload increments of 25 W at consecutive 3 minute intervals. Initial work load was zero load. All patients pedaled at a constant speed of 44 revolutions/min to ensure a constant workload. Expired gas collection and measurement of hemodynamic variables were performed during the last minute of peak exercise effort.

At peak exercise, all patients reported severe general body fatigue, severe leg discomfort, and moderate to severe dyspnea. No exercise test was stopped because of chest pain or dysrhythmia. For all patients, the respiratory exchange ratio ($\dot{V}CO_2/\dot{V}O_2$, the quotient of carbon dioxide production and oxygen consumption) was increased significantly at peak exercise (mean 1.07) compared with resting conditions, indicating that patients had achieved anaerobic threshold. Thus, oxygen consumption at peak exercise probably represented a close approximation to the true maximal $\dot{V}O_2$.[15]

Drug protocol: Doses of digoxin and furosemide were kept constant during the addition of minoxidil therapy. Because the pharmacologic half-life of minoxidil is 12 to 18 hours, an incremental dosage schedule was designed in order to minimize the probability of an undesirable hemodynamic effect. The initial test dose of 2.5 mg was given orally, and supine hemodynamic measurements were recorded serially every 30 minutes. Additional doses of minoxidil were administered every 90 minutes in log-dose fashion; the second dose was 2.5 mg, the third 5.0 mg, the fourth 10 mg, and so on. We used a hemodynamic end point of an increase in supine, resting cardiac output of at least 25% over baseline value. All patients achieved that end point during initial dose titration without demonstrating the previously defined withdrawal criteria of systolic blood pressure less than 90 mm Hg or heart rate greater than 120 beats/min. Subsequent doses were calculated

All data are expressed as mean ± standard deviation (SD).

* Fick cardiac output. † $p < 0.05$ minoxidil treatment compared with control at rest. ‡ $p < 0.05$ minoxidil treatment compared with control during exercise.

AP = mean arterial pressure; A-VO_2 = arteriovenous oxygen content difference; CE = conventional therapy at peak exercise; CI = cardiac index; Cond = condition of measurement; CR = conventional therapy at rest; HR = heart rate; LVFP = left ventricular filling pressure; ME = minoxidil therapy on exercise; MR = minoxidil therapy at rest; PA = mean pulmonary arterial pressure; PVR = pulmonary vascular resistance; RA = mean right atrial pressure; SVI = stroke volume index; SVR = systemic vascular resistance; $\dot{V}O_2$ = oxygen consumption.

as the sum of the titration doses and administered every 12 hours. The mean dose administered was 15.2 mg (range 7.5 to 22.5). Repeat exercise testing after short-term minoxidil therapy was performed 2 hours after the fifth dose. In 1 patient an unstable pattern of angina pectoris developed during minoxidil therapy before the second exercise test, and the patient could not be entered into the study. Minoxidil was administered to 2 additional patients under the same protocol, but the pulmonary arterial catheter was removed because of infection before repeat exercise testing on the drug; data from these patients are also not included in the present series. Both of these patients had increased resting cardiac output without side effects.

Data analysis: Comparisons between treatment groups and between rest and exercise conditions were made using a 2-factor analysis of variance (ANOVA) for repeated measures. Significant interaction effects were confirmed by the Newman-Keuls test for comparisons. The level of significance was chosen as 0.05.

Results

Individual patient data are summarized in Table I.

Cardiac output: During conventional therapy, the cardiac index increased from 1.99 ± 0.38 liters/min/m^2 at rest to 2.88 ± 0.79 at peak exercise. After minoxidil therapy, the cardiac index increased to 2.64 ± 0.33 liters/min/m^2 at rest and 3.55 ± 0.84 at maximal exercise. As shown in Figure 1, the increases in cardiac index were statistically significant both at rest and on exercise ($p < 0.02$). Thus, minoxidil primarily increased cardiac output at rest and did not blunt the additional increase due to exercise. Drug treatment and exercise contributed independently to the increase in cardiac output seen with exercise in patients in the drug-treated group. No significant statistical interaction effects were found.

The relative contributions of heart rate and stroke volume to cardiac output were examined next (Fig. 2). With conventional therapy, the heart rate increased from 88 ± 13 beats/min at rest to 103 ± 18 at peak exercise. After minoxidil treatment, the heart rate was not significantly different ($p < 0.10$) from conventional therapy either at rest (94 ± 9 beats/min) or on maximal exertion (105 ± 11). However, at rest 3 patients had an increase in heart rate of more than 10 beats/min after minoxidil. The stroke volume index was 23.1 ± 5.8 ml/beat/m^2 at rest and increased to 29.6 ± 12.4 at peak exercise during conventional therapy. After the addition of minoxidil, the stroke volume index increased significantly ($p < 0.02$) to 28.4 ± 5.0 ml/beat/m^2 at rest and 33.9 ± 8.7 at maximal exercise. In two patients, stroke volume decreased slightly at rest after minoxidil. The cardiac index was preserved by a slight increase in heart rate.

No interaction between drug treatment and exercise was found for stroke volume. These data suggest that the major effect of minoxidil is to increase stroke volume to a similar degree both at rest and on exercise, without a substantial effect on heart rate.

Systemic and intracardiac pressure and resistance: During conventional therapy, mean arterial pressure increased from 94 ± 16 at rest to 101 ± 19 mm Hg at peak exercise. After the addition of minoxidil, mean arterial pressure was lower but still increased from 83 ± 12 at rest to 96 ± 16 mm Hg at peak exercise. The small decrease in resting blood pressure when minoxidil was added was significant ($p < 0.05$) and was more than 15 mm Hg in 3 patients although no patient had symptomatic hypotension. At peak exercise, there was no significant change ($p > 0.10$) in mean arterial pressure after minoxidil administration. However, there was a significant drug-exercise statistical interaction ($p < 0.02$), indicating that the increase in mean arterial pressure from rest to exercise was actually higher after minoxidil treatment than on conventional therapy.

During conventional therapy, systemic vascular resistance fell during exercise from 2,050 ± 722 to 1,500 ± 830 dynes·s/cm^5 (p = NS). During minoxidil therapy, systemic vascular resistance decreased from 1,325 ± 374 to 1,206 ± 589 dynes·s/cm^5 (p = NS). There was a significant statistical interaction between minoxidil and exercise such that the reduction in systemic vascular resistance from rest to exercise was blunted by minoxidil ($p < 0.05$).

Left ventricular filling pressure was elevated at 20 ± 9 mm Hg on conventional therapy and increased further with exercise to 29 ± 10 mm Hg. After the addition of minoxidil, there was no significant change in left ventricular filling pressure at rest or exercise. However, changes in mean filling pressure were erratic, and 4 patients had a decrease of more than 10 mm Hg at rest after minoxidil.

Pulmonary vascular resistance was elevated in the patients while on conventional therapy at 251 ± 132 dynes·s/cm^5, and did not change with exercise (242 ± 134, p = NS). The addition of minoxidil significantly decreased pulmonary vascular resistance both at rest (190 ± 87 dynes·s/cm^5) and on exercise (207 ± 112) ($p < 0.05$).

Oxygen consumption and exercise performance: Oxygen consumption measured at rest was 3.7 ± 0.8 ml/kg/min, which indicated that the total body metabolic requirements for oxygen at rest were not signifi-

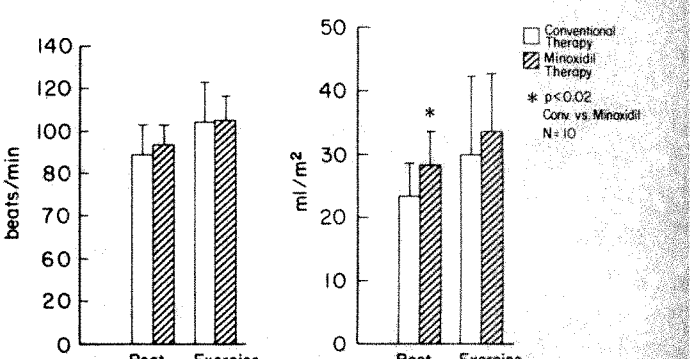

FIGURE 2. Effect of short-term oral minoxidil administration on heart rate (**left**) and stroke volume (**right**) at rest and exercise in patients with severe heart failure. **Open bars** represent values on conventional therapy alone; **cross-hatched bars** represent values after the addition of minoxidil. There was a significant increase in resting stroke volume ($p < 0.02$) after minoxidil treatment.

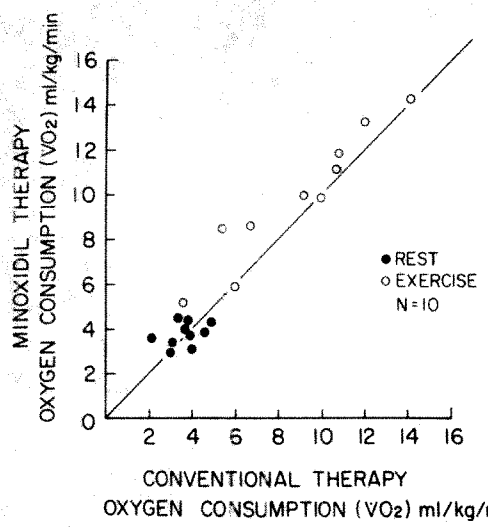

FIGURE 3. Effect of minoxidil therapy compared with conventional therapy on peak oxygen consumption in patients with severe chronic heart failure. Each **point** represents the peak oxygen consumption for the same patient while on conventional therapy and after the addition of minoxidil. **Solid circles** indicate resting conditions and **open circles** indicate maximal symptom-limited exercise. The **solid line** is the line of identity. Six of 10 patients showed higher peak $\dot{V}O_2$ on minoxidil therapy compared with conventional therapy (that is, data points above the line of identity).

cantly different from normal in these patients. Resting oxygen consumption was unchanged (3.8 ± 0.6 ml/kg/min) after the addition of minoxidil. Oxygen consumption at maximal exercise only increased to 8.9 ± 3.2 ml/kg/min on conventional therapy. After administration of minoxidil, maximum oxygen consumption was 18% higher (10.5 ± 2.4 ml/kg/min) than with conventional therapy. As shown in Figure 3, six of 10 patients had slightly improved maximal oxygen consumption after minoxidil therapy. These data principally reflect an increase of 1 work load stage in 4 of the patients. During conventional therapy, the median peak exercise work load was 25 W (range 0 to 75) and the median exercise duration was 6.0 minutes (range 3 to 12). After the addition of minoxidil, the median peak work load increased to 50 W (range 0 to 75) at a median exercise duration of 9.0 minutes (range 3 to 12).

Minoxidil decreased the arteriovenous oxygen content difference at rest from 7.7 ± 1.5 to 5.8 ± 0.9 ml O_2/dl blood ($p < 0.001$) and on exercise from 12.9 ± 2.5 to 11.7 ± 2.5 ($p < 0.001$). Therefore, minoxidil increased cardiac output at rest and on exercise and oxygen consumption on exercise despite a narrowing of the arteriovenous oxygen content difference. Arterial oxygen saturation was normal and nearly fully saturated at rest and on exercise (0.95 ± 0.01), and was unchanged by minoxidil.

Clinical follow-up during long-term minoxidil therapy: Clinical follow-up was planned for 6 weeks. However, only 5 of 10 patients completed the entire follow-up period. Minoxidil was discontinued because of an intercurrent subendocardial myocardial infarction in 1 patient, and 4 other patients refused to comply with the outpatient protocol, which required frequent return clinic visits and medication adjustment. All of the remaining patients reported symptomatic improvement of at least 1 functional class. No patient had symptomatic hypotension or tachycardia.

All patients developed worsening dependent edema which required continued dietary sodium restriction and increased diuretic dosage to maintain a stable body weight. At the sixth week of therapy, the mean furosemide dose was 220 mg/day, compared with a mean dose of 118 mg/day before minoxidil administration. One patient required concomitant daily administration of 5 mg of metolazone. The only female patient in the follow-up group developed increased facial hair growth, which was treated with a calcium thioglycollate depilatory.[16] Angina pectoris also developed while she was taking minoxidil, but improved when the drug was discontinued after the 6 week trial period. Another patient developed worsening of an antecedent benign essential tremor, which responded to low doses of oral diazepam. No other side effects of minoxidil were observed in our patient cohort.

Since minoxidil administration has been associated with the development of pericardial effusion in some patients with hypertension,[17] serial M-mode echocardiograms were obtained to detect this potential complication. Two patients had small effusions before minoxidil therapy, which did not change during drug administration. None of the remaining patients, including the 4 patients observed for the entire 6 weeks, had a new pericardial effusion.

Discussion

Minoxidil is a direct-acting arteriolar vasodilator that may have several advantages over other currently available compounds of this class. In hypertensive patients it is a powerful peripheral vasodilator which may be efficacious even when a patient does not respond to other drugs, including hydralazine. It has a prolonged duration of action and can be administered on a once- or twice-daily schedule, which can increase patient compliance. It has no direct chronotropic or inotropic activity. The drug does not appear to result in orthostatic hypotension. Also, it is chemically distinct, and unlike hydralazine is not associated with a lupus-like syndrome or peripheral neuropathy. Tachyphylaxis is not seen during long-term administration for hypertension.[18]

Our data confirm previous preliminary studies which reported salutary hemodynamic effects of minoxidil at rest in patients with chronic congestive heart failure.[10–12] After minoxidil administration, stroke volume increased by 19% with a small but insignificant change in heart rate, accounting for a 25% increase in cardiac output. Systemic vascular resistance decreased by 35%, without significant effects on right atrial, pulmonary artery, or left ventricular filling pressure. Some patients had a substantial decrease in resting blood pressure. These effects are similar to those of other predominantly arteriolar vasodilators such as hydralazine.[6]

Improvement in stroke volume at the same left ventricular filling pressure suggests improved left ventricular performance at rest.

Our results also document beneficial hemodynamic effects of minoxidil at maximal symptom-limited exercise in this cohort of patients with severe chronic heart failure. After minoxidil treatment, there was a significant increase in cardiac output at peak exercise compared with conventional therapy alone (Fig. 1). This increase in cardiac output was accounted for by an increase in stroke volume and a smaller increase in heart rate. The effects of minoxidil and exercise on cardiac output were independent of one another.

Short-term administration of minoxidil resulted in a small but significant increase in maximal oxygen consumption because peak work load and exercise duration increased in some patients. It is possible that the improved arterial oxygen transport due to increased cardiac output allowed skeletal muscle to maintain aerobic metabolism while exercising to a higher work load. However, short-term objective improvement in work performance has not been readily demonstrated for other vasoactive drugs including hydralazine,[6,19] nitrates,[3,20] prazosin,[4,19] and phentolamine[21] despite salutary effects on exercise hemodynamics, perhaps because of a defect in muscle oxygen utilization or because of vascular shunting which prevents muscle oxygen delivery.[19,22] We expected minoxidil to have the same effects on exercise capacity and maximal oxygen uptake as observed in our other vasodilator studies.[4,6,19] Our observations require further confirmation.

One patient developed angina pectoris during short-term administration of minoxidil, while another developed a subendocardial infarction during follow-up. These complications have been observed with other vasodilators in patients with ischemic heart disease, especially during hydralazine administration.[23,24] Because we are not able to predict a priori which patients will develop ischemic side effects, we observe coronary heart disease patients very carefully after starting vasodilator therapy.

During long-term administration of minoxidil 5 patients reported subjective improvement in exercise tolerance, dyspnea, and fatigue. The major side effect of worsening dependent edema was caused by the well-recognized sodium-retaining properties of the drug[25] and was adequately controlled by careful adjustment of diuretic therapy. Even in patients who have fluid balance, we have found it prudent to increase furosemide and simultaneously start small doses of metolazone before hospital discharge. Otherwise, fluid retention may occur rapidly and prove difficult to control once it is established. Three patients who originally received minoxidil, including 2 who had massive edema, subsequently received hydralazine. The short-term hemodynamic effect was equal to that on minoxidil therapy, with no edema on outpatient follow-up study.

Minoxidil-related hypertrichosis occurs in about 80% of patients taking the drug for 1 year,[26] and is thought to be due to an increase in blood flow to the skin.[27] Hirsutism appears to be dose-related and readily reversible on discontinuation of the drug. In female patients, concomitant use of a calcium thyoglycollate depilatory may be necessary.

Pericardial effusion has been reported to occur in about 3% of hypertensive patients taking minoxidil,[17] but worsening effusion was not seen in any of our patients. Nonspecific electrocardiographic T-wave changes have been reported in up to 60% of patients with long-term minoxidil therapy (manufacturer's data, Upjohn Laboratories, Kalamazoo, Michigan). These changes may have represented left ventricular enlargement in the patients with hypertension. Similar changes did not occur during the course of the present study.

In view of our experience with chronic administration of minoxidil, we recommend that the drug be given with much caution to patients with active ischemic heart disease. After dosage titration to a hemodynamic end point, concomitant administration of furosemide and perhaps metolazone should be started in order to control edema. Frequent follow-up examination (for example, twice weekly) is necessary for the first 2 or 3 weeks of therapy in order to avoid rapid and difficult-to-control fluid retention. Female patients should be warned about the expected increase in facial hair. Although the development or worsening of pericardial effusion was not observed in our small group of patients, serial monthly echocardiography seems clinically prudent at this time.

Acknowledgment

Statistical analysis was performed by Moraye Bear, whose contribution is gratefully acknowledged. Special thanks to Erick Burkhart, David Mickle, and Frank Shellock for technical assistance. We also wish to thank Dr. Harvey Brown for the use of laboratory facilities, Dr. William Martin of Upjohn Laboratories for providing minoxidil, Patricia Allen for editorial assistance, Joyce Nunn for secretarial assistance, Lance Laforteza for graphics, and Patricia Edwards for photography.

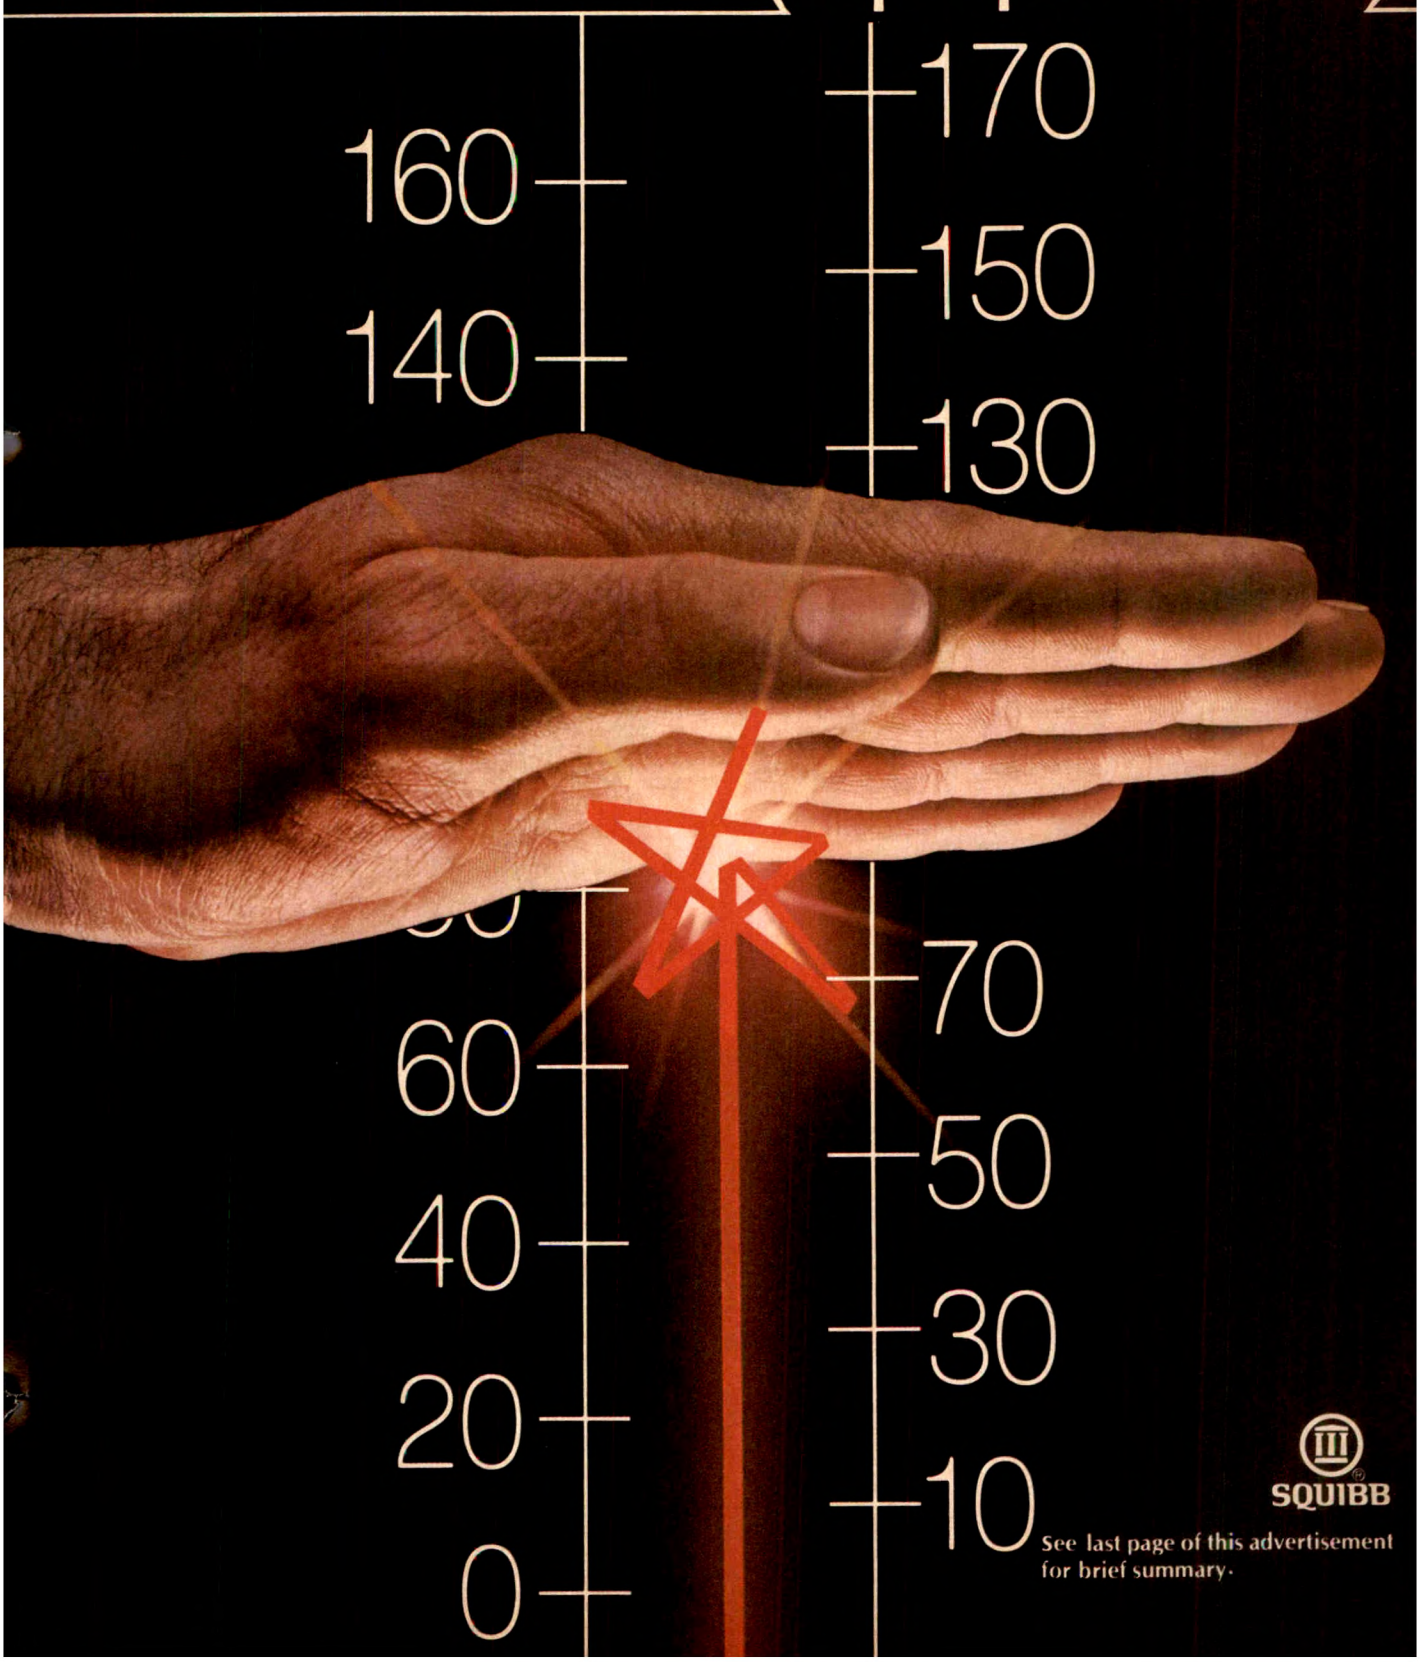
Designed to achieve your therapeutic goals in hypertension

CAPOTEN® (captopril tablets)



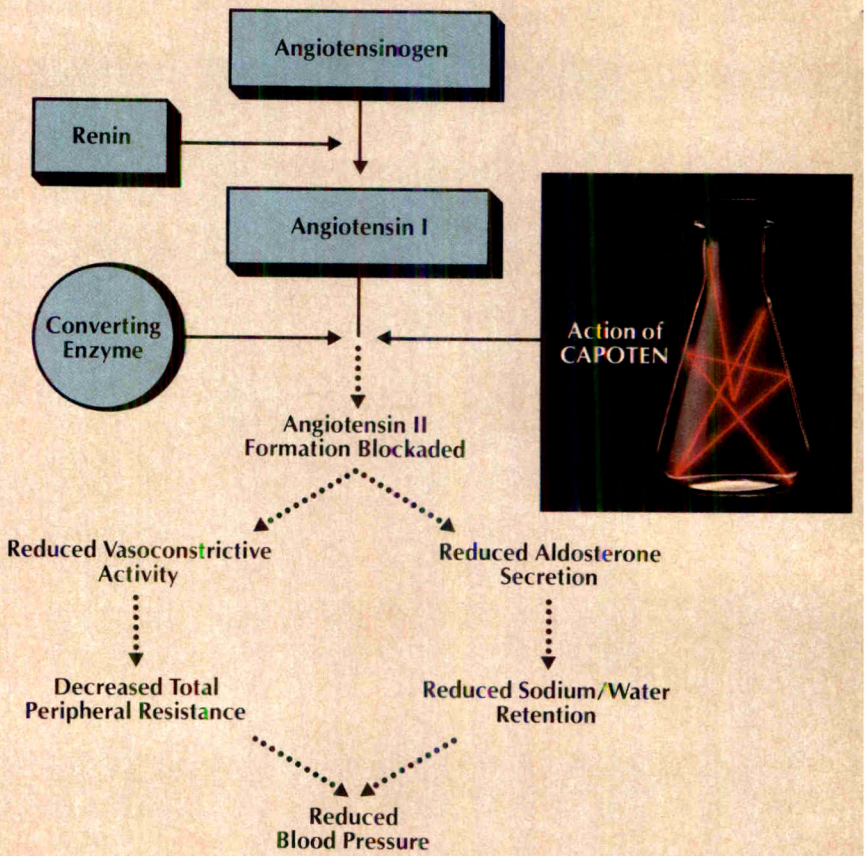
SQUIBB

See last page of this advertisement for brief summary.

ACE* INHIBITOR

CAPOTEN® (captopril tablets)

Because of its specific action within the renin-angiotensin-aldosterone (RAA) system, CAPOTEN enables you to reliably control blood pressure in a diverse group of hypertensive patients.



For hypertensive patients:

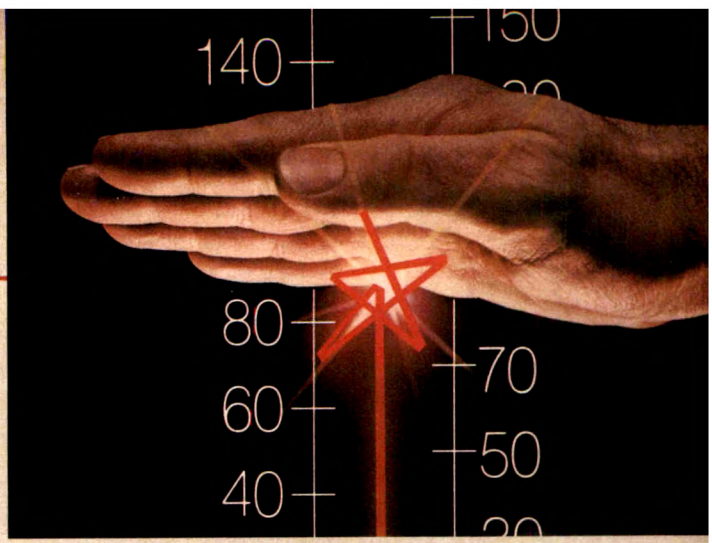
who experience unacceptable side effects with beta blockers, antiadrenergic agents, or vasodilators

whose blood pressure is uncontrolled by standard multidrug regimens

who have concomitant conditions contraindicating use of other antihypertensive agents

*Angiotensin Converting Enzyme

SQUIBB



A design that controls blood pressure without the following usual antihypertensive side effects*

- ▶ No cardiac depression
- ▶ No glucose intolerance
- ▶ No bradycardia
- ▶ No mental depression
- ▶ No sleep disturbances
- ▶ No nasal congestion
- ▶ No hypokalemia

- ▶ Rare impotence/loss of libido
- ▶ Rare bronchospasm
- ▶ Rare tachycardia
- ▶ Rare fatigue

ACE INHIBITOR

CAPOTEN®
(captopril tablets)

*Please see brief summary of prescribing information on the last page of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

ACE* INHIBITOR

CAPOTEN® (captopril tablets)

Designed to control blood pressure even when coexisting disorders complicate hypertension management

Unlike some other antihypertensive agents, CAPOTEN is appropriate for use in the presence of a wide range of cardiovascular and metabolic disorders that often coexist with hypertension.

- **Bronchospastic disease**
- **Cardiac arrhythmias**
- **Congestive heart failure**
- **Diabetes mellitus**
- **Hepatic disease**

Designed to control blood pressure when conventional multidrug regimens have proven inadequate

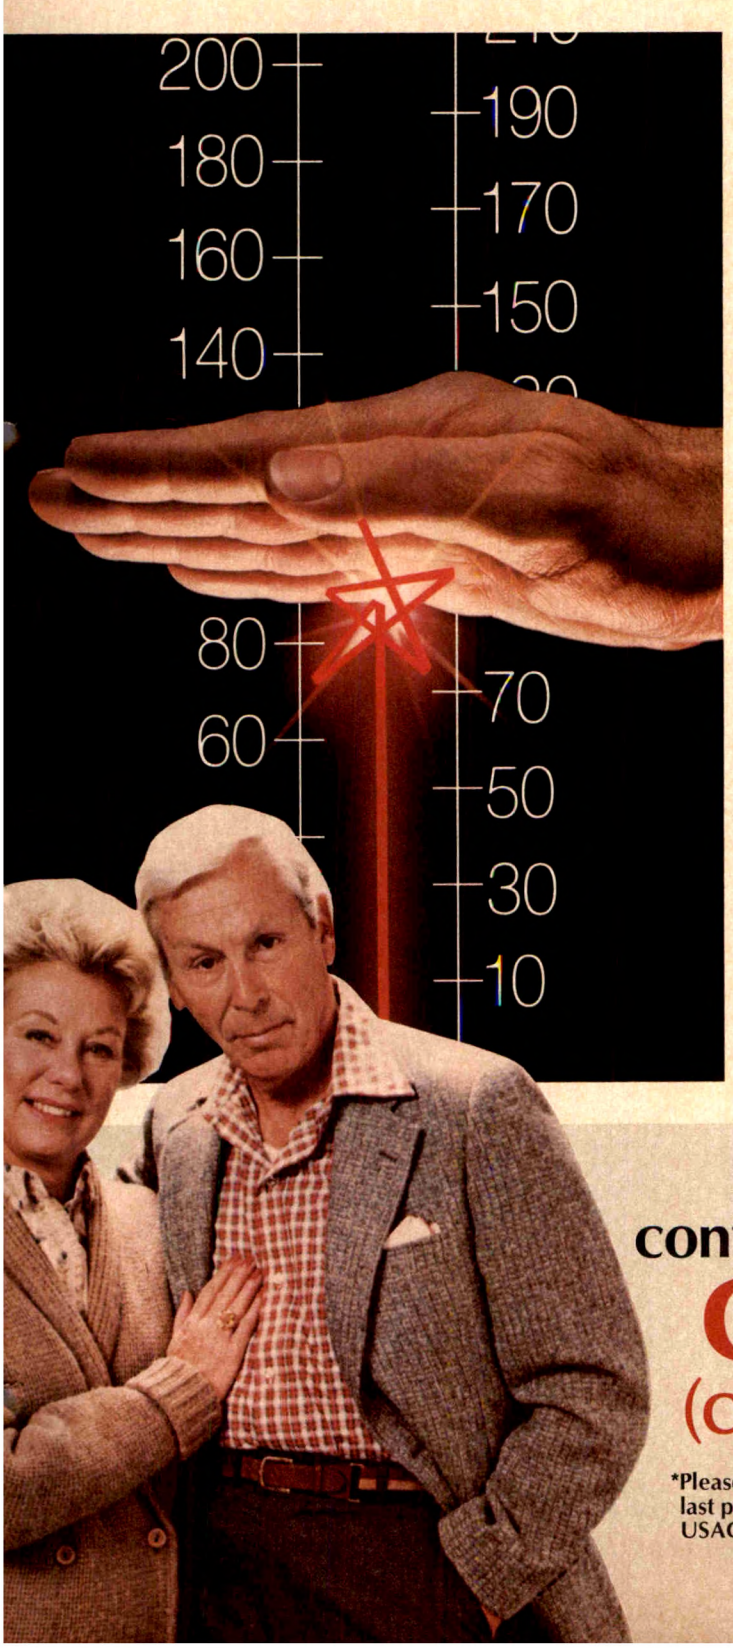
In scores of clinical studies, the effectiveness of CAPOTEN in lowering elevated blood pressure has been proven in many kinds of hypertension—even in those types that are most difficult to treat.

- **Essential hypertension**
- **Hypertension resistant to standard triple therapy (STT)**
- **Hypertension associated with low, normal, and high plasma renin levels**
- **Renovascular hypertension**

*Angiotensin Converting Enzyme

Designed to achieve your therapeutic goals in hypertension

SQUIBB



Effective blood pressure control

▶ Routine monitoring procedures are recommended because serious side effects (neutropenia/agranulocytosis, proteinuria) have been associated with CAPOTEN.*

▶ Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.

▶ Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.

▶ Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.

▶ The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.

In hypertension... confidence comes with

CAPOTEN®

(captopril tablets)

*Please see brief summary of prescribing information on the last page of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

Captopril Tablets

DESCRIPTION: Capoten (captopril) is a specific competitive inhibitor of angiotensin I-converting enzyme (ACE), the enzyme responsible for converting angiotensin I to angiotensin II.

INDICATIONS: Because serious adverse effects have been reported (see WARNINGS), Capoten is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects. Usually, multidrug regimens include combinations of a diuretic, a sympathetic nervous system-active agent (such as a beta-blocker) and a vasodilator.

Capoten (captopril) is effective alone, but in the population described above, it should usually be used in combination with a thiazide-type diuretic. The blood pressure lowering effects of captopril and thiazides appear to be additive.

WARNINGS: Proteinuria—Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. Existence of prior renal disease increased the likelihood of development of proteinuria. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued, but some patients had persistent proteinuria. The BUN and creatinine were seldom altered in the proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related; this is uncertain since patients were not biopsied prior to treatment and membranous glomerulopathy may be associated with hypertension in absence of captopril therapy. Since most cases of proteinuria occurred by the 8th month of captopril therapy, patients on captopril should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine—the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis—Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller, and it is sufficient in these patients to have white blood cell counts every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension—Excessive hypotension was rarely seen in hypertensive patients but is a possible consequence of captopril use in severely salt/volume depleted persons such as those treated vigorously with diuretics, e.g., patients with severe congestive heart failure (see PRECAUTIONS [Drug Interactions]).

PRECAUTIONS: General: *Impaired Renal Function*—Some patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine after reduction of blood pressure with captopril. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible (see DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]). *Surgery/Anesthesia*—During major surgery or anesthesia with agents that produce hypotension, captopril will block angiotensin II formation secondary to compensatory renin release; if hypotension occurs and is considered due to this mechanism, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy*—A precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretic therapy and those on severe dietary salt restriction or dialysis. The possibility of hypotensive effects can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose. If hypotension occurs, place the patient in a supine position and, if necessary, administer an I.V. infusion of normal saline. This transient hypotensive response is not a contraindication to further doses which can be given without difficulty once the blood pressure has increased after volume expansion.

Agents Causing Renin Release—Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity—The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium—Since captopril decreases aldosterone production, elevation of serum potassium may occur. Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. If the patient has received spironolactone at any time up to several months prior to captopril therapy, determine the serum potassium frequently since the effect of spironolactone persists.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential.

Animal Toxicology: Chronic oral toxicity studies were conducted in rats (2 years), dogs (47 weeks; 1 year), mice (2 years), and monkeys (1 year). Significant drug-related toxicity included effects on hematopoiesis, renal toxicity, erosion/ulceration of the stomach, and variation of retinal blood vessels. Reductions in hemoglobin and/or hematocrit values were seen in mice, rats, and monkeys at doses 50 to 150 times the maximum recommended human dose (MRHD). Anemia, leukopenia, thrombocytopenia, and bone marrow suppression occurred in dogs at doses 8 to 30 times MRHD. The reductions in hemoglobin and hematocrit values in rats and mice were only significant at 1 year and returned to normal with continued dosing by the end of the study. Marked anemia was seen at all dose levels (8 to 30 times MRHD) in dogs, whereas moderate to marked leukopenia was noted only at 15 and 30 times MRHD and thrombocytopenia at 30 times MRHD. The anemia could be reversed upon discontinuation of dosing. Bone marrow suppression occurred to a varying degree, being associated only with dogs that died or were sacrificed in a moribund condition in the 1-year study. However, in the 47-week study at a dose 30 times MRHD, bone marrow suppression was found to be reversible upon continued drug administration. Captopril caused hyperplasia of the juxtaglomerular apparatus of the kidneys at doses 7 to 200 times the MRHD in rats and mice, at 20 to 60 times MRHD in monkeys, and at 30 times the MRHD in dogs. Gastric erosions/ulcerations were increased in incidence at 20 and 200 times MRHD in male rats and at 30 and 65 times MRHD in dogs and monkeys, respectively. Rabbits developed gastric and intestinal ulcers when given oral doses about 30 times MRHD for only 5 to 7 days. In the two-year rat study, irreversible and progressive variations in the caliber of retinal vessels (focal sacculations and constrictions) occurred at all dose levels (7 to 200 times MRHD) in a dose-related fashion. The effect was first observed in the 88th week of dosing, with a progressively increased incidence thereafter, even after cessation of dosing.

Pregnancy: Category C—Captopril was embryocidal in rabbits when given in doses 2 to 6 times (on a mg/kg basis) the maximum recommended human dose. The marked embryocidal effect in rabbits was most probably due to the particularly marked decrease in blood pressure caused by the drug in this species. Captopril given to pregnant rats at 400 times the recommended human dose continuously during gestation and lactation reduced neonatal survival. No teratogenic effects (malformations) have been seen at large doses of captopril in hamsters, rats, and rabbits.

There are no adequate and well-controlled studies in pregnant women. Captopril should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Concentrations of captopril in human milk are about 1% of those in maternal blood. The effect of low levels of captopril on the nursing infant has not been determined. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age with secondary hypertension and varying degrees of renal insufficiency. Dosage on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving about 4000 patients.

Renal—One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients but relationship to drug use is uncertain.

Hematologic—Neutropenia/agranulocytosis (probably drug related) occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic—Rash (usually maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the first 4 weeks of therapy. The rash is usually mild and disappears within a few days of dosage reduction, short-term treatment with an antihistaminic agent, and/or discontinuing therapy; remission may occur even if captopril is continued. Pruritus, without rash, in about 2 of 100 patients. Between 7 and 10% of patients with skin rash have shown an eosinophilia and/or positive ANA titers. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients—reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular—Hypotension in about 2 of 100 patients. See PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 100 patients.

Dysgeusia—About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Weight loss may be associated with the loss of taste. Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although a causal relationship has been established. A single case of hepatocellular injury with secondary cholestasis has been reported in association with captopril use. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. Dosage must be individualized.

Give consideration to recent antihypertensive drug therapy, extent of blood pressure elevation, salt restriction, and other circumstances before initiating therapy. If possible, discontinue the patient's previous antihypertensive drug regimen for one week before starting captopril. Initial dose of CAPOTEN (captopril) is 25 mg t.i.d. If satisfactory blood pressure reduction is not achieved after 1 or 2 weeks, dose may be increased to 50 mg t.i.d. If the blood pressure has not been satisfactorily controlled after another 1 to 2 weeks, add a modest dose of a thiazide-type diuretic (e.g., hydrochlorothiazide, 25 mg daily). The diuretic dose may be increased at 1- to 2-week intervals until its highest usual antihypertensive dose is reached. If further blood pressure reduction is required, CAPOTEN (captopril) may be increased to 100 mg t.i.d. and then, if necessary, to 150 mg t.i.d. (while continuing the diuretic). The usual dose range is 25 to 150 mg t.i.d. A maximum daily dose of 450 mg CAPOTEN (captopril) should not be exceeded.

For patients with accelerated or malignant hypertension, when temporary discontinuation of current antihypertensive therapy is not practical, or when prompt titration to more normotensive blood pressure levels is indicated, current antihypertensive medication may be stopped and CAPOTEN (captopril) dosage promptly initiated at 25 mg t.i.d., under close medical supervision. The daily dose of CAPOTEN (captopril) may be increased every 24 hours until a satisfactory blood pressure response is obtained or the maximum captopril dose is reached. In this regimen, addition of a more potent diuretic, e.g., furosemide, may also be indicated. Beta-blockers may also be used in conjunction with captopril therapy (see PRECAUTIONS [Drug Interactions]), but the effects of the 2 drugs are less than additive.

Dosage Adjustment in Renal Impairment—Because CAPOTEN (captopril) is excreted primarily by the kidneys, excretion rates are reduced in patients with impaired renal function. These patients will take longer to reach steady-state captopril levels and will reach higher steady-state captopril levels for a given daily dose than patients with normal renal function. Therefore, these patients may respond to smaller or less frequent doses. Accordingly, for patients with significant renal impairment, initial daily dosage of CAPOTEN (captopril) should be reduced, and smaller increments utilized for titration, which should be quite slow (1- to 2-week intervals). After desired therapeutic effect has been achieved, dose should be slowly back-titrated to determine minimal effective dose. When concomitant diuretic therapy is required, a loop diuretic (e.g., furosemide), rather than a thiazide diuretic, is preferred in patients with severe renal impairment.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

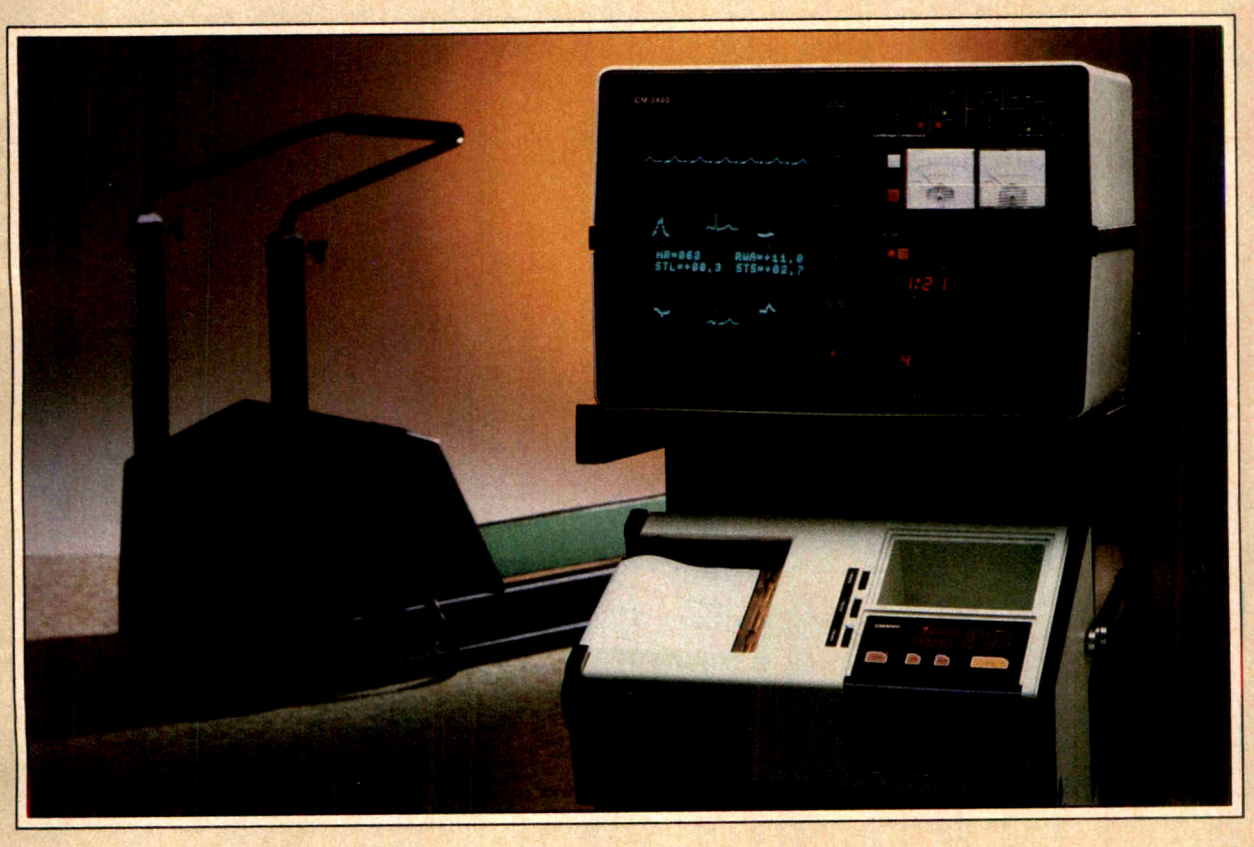
Picker International. The Source for Stress Test Systems.



Observer™...an Unbeatable Combination of Value and Capability

Capability. This new computerized System contains everything you need to perform smooth, error-free stress tests. Observer™ offers three, twelve, and fifteen lead ECG write-outs, signal averaging to suppress muscle artifact and noise, automatic sequencing of treadmill and recorder, and more. During the test, ST level and slope, heart rate and R-wave amplitude are continuously computed and displayed. These measurements are accumulated and presented as trend graphs on the final report. Cursor controls enable the physician to set or reposition the ST measurement point without having to interrupt the test.

Value. Observer™ has been engineered exclusively for the health care professional. Its versatile, modular design allows us to offer you a fully capable system in a configuration that's especially suited to your particular laboratory and budgetary requirements.

So, come to the Source for Stress Test Systems. And ask your Cambridge representative about Observer™ today. Or write or phone us direct at: Picker International, Inc., Cambridge Medical Instruments Division, 73 Spring Street, Ossining, NY 10562. Tel: 914/941-8100.

Toronto Western Hospital

256 pages ISBN 0-669-04505-5 $25.95

This book provides a concise, clinical treatment of diagnosis and treatment of cardiovascular disease in the elderly. While it is largely devoted to discussion of specific problems, it provides ample discussion of changes to the aging cardiovascular system, with special reference to features that are pathological in younger people but normal in the elderly. A section on pharmacology covers aging and pharmacodynamics and describes specific cardiovascular drugs.

CONTENTS: **1.** Defining the Problems. **2.** Aging and the Heart. **3.** Assessment of the Elderly Patient with Cardiovascular Disease. **4.** Pharmacological Aspects of Aging. **5.** Coronary Artery Disease. **6.** Hypertension. **7.** Valvular Heart Disease. **8.** Myocardial and Pericardial Disease. **9.** Congestive Heart Failure. **10.** Arrhythmias. **11.** Pacemaker Therapy. **12.** Miscellaneous Conditions. Index.

For **every** professional with an interest in Exercise and the Heart.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books AJCK2
Box C-757, Brooklyn, New York 11205

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($38.00 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

- ☐ Full payment enclosed, publisher pays shipping.
- ☐ Please bill me, plus cost of shipping.
- ☐ Charge my credit card: ☐ MasterCard ☐ Visa.

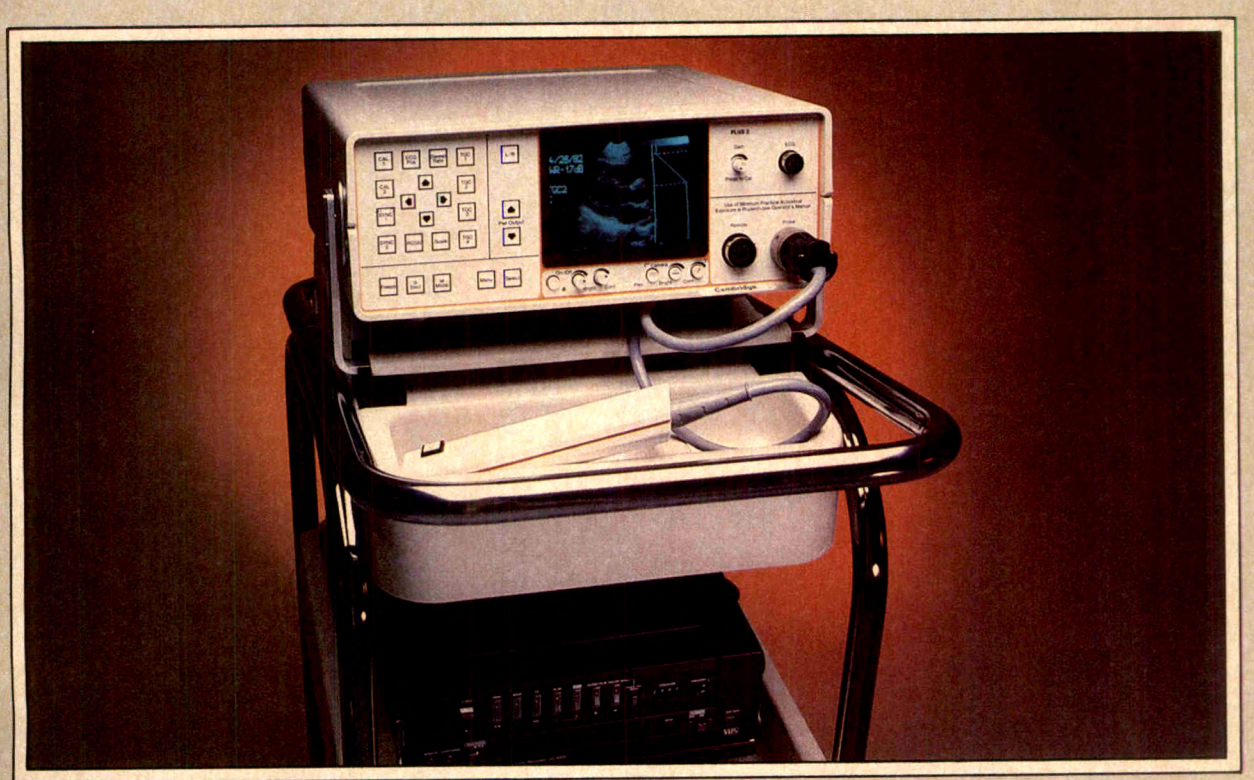
Picker International. The Source for Echocardiography.



Introducing Plus 2, A Revolutionary Portable Ultrasound System Offering High Quality M-mode And 2-D Imaging.

Now conduct echocardiography studies in your office, clinic, or CCU. Plus 2 is the only dual purpose echo system that's so portable it can go wherever you go.

Picker International has combined the latest microprocessor and ultrasound technology in a lightweight unit that is dramatically smaller and more versatile than competitive units. In clinical situations you can have this powerful diagnostic tool at bedside for your critically ill patients. And, you can easily take Plus 2 on the road with you for examination of patients in localities where equipment is not available.

Best of all, Picker International's Plus 2 portable ultrasound system is less than half the cost of other systems offering comparable diagnostic capabilities. And Plus 2 is backed by Picker International Regional Service Centers worldwide, giving you prompt, dependable service.

So come to the Source for portability in ultrasound systems. Call your Cambridge representative today. Or contact the Cambridge Division, Picker International, Inc., 73 Spring Street, Ossining, NY 10562. Tel: 914/941-8100.

PICKER INTERNATIONAL

Picker International is the source for cardiography systems.

To you, this is important.

Having a single source dedicated to meeting all of your cardiography equipment needs can save time in your decision making process.

And, a single source for your service and supply needs can save you time after your purchase, as well.

This three channel ECG with its versatile interactive memory is just one of the exciting new products available from our Cambridge Medical Instruments Group. Others include automatic and manual single channel ECG's; conventional and computer assisted stress test systems; ambulatory and telemetry monitoring systems; and the first truly portable ultrasound system.

We'd like to tell you more about our cardiography systems. Please write Picker International, Inc., 73 Spring St., Ossining, NY 10562; Telephone 914/941-8100 or Telex 137337.

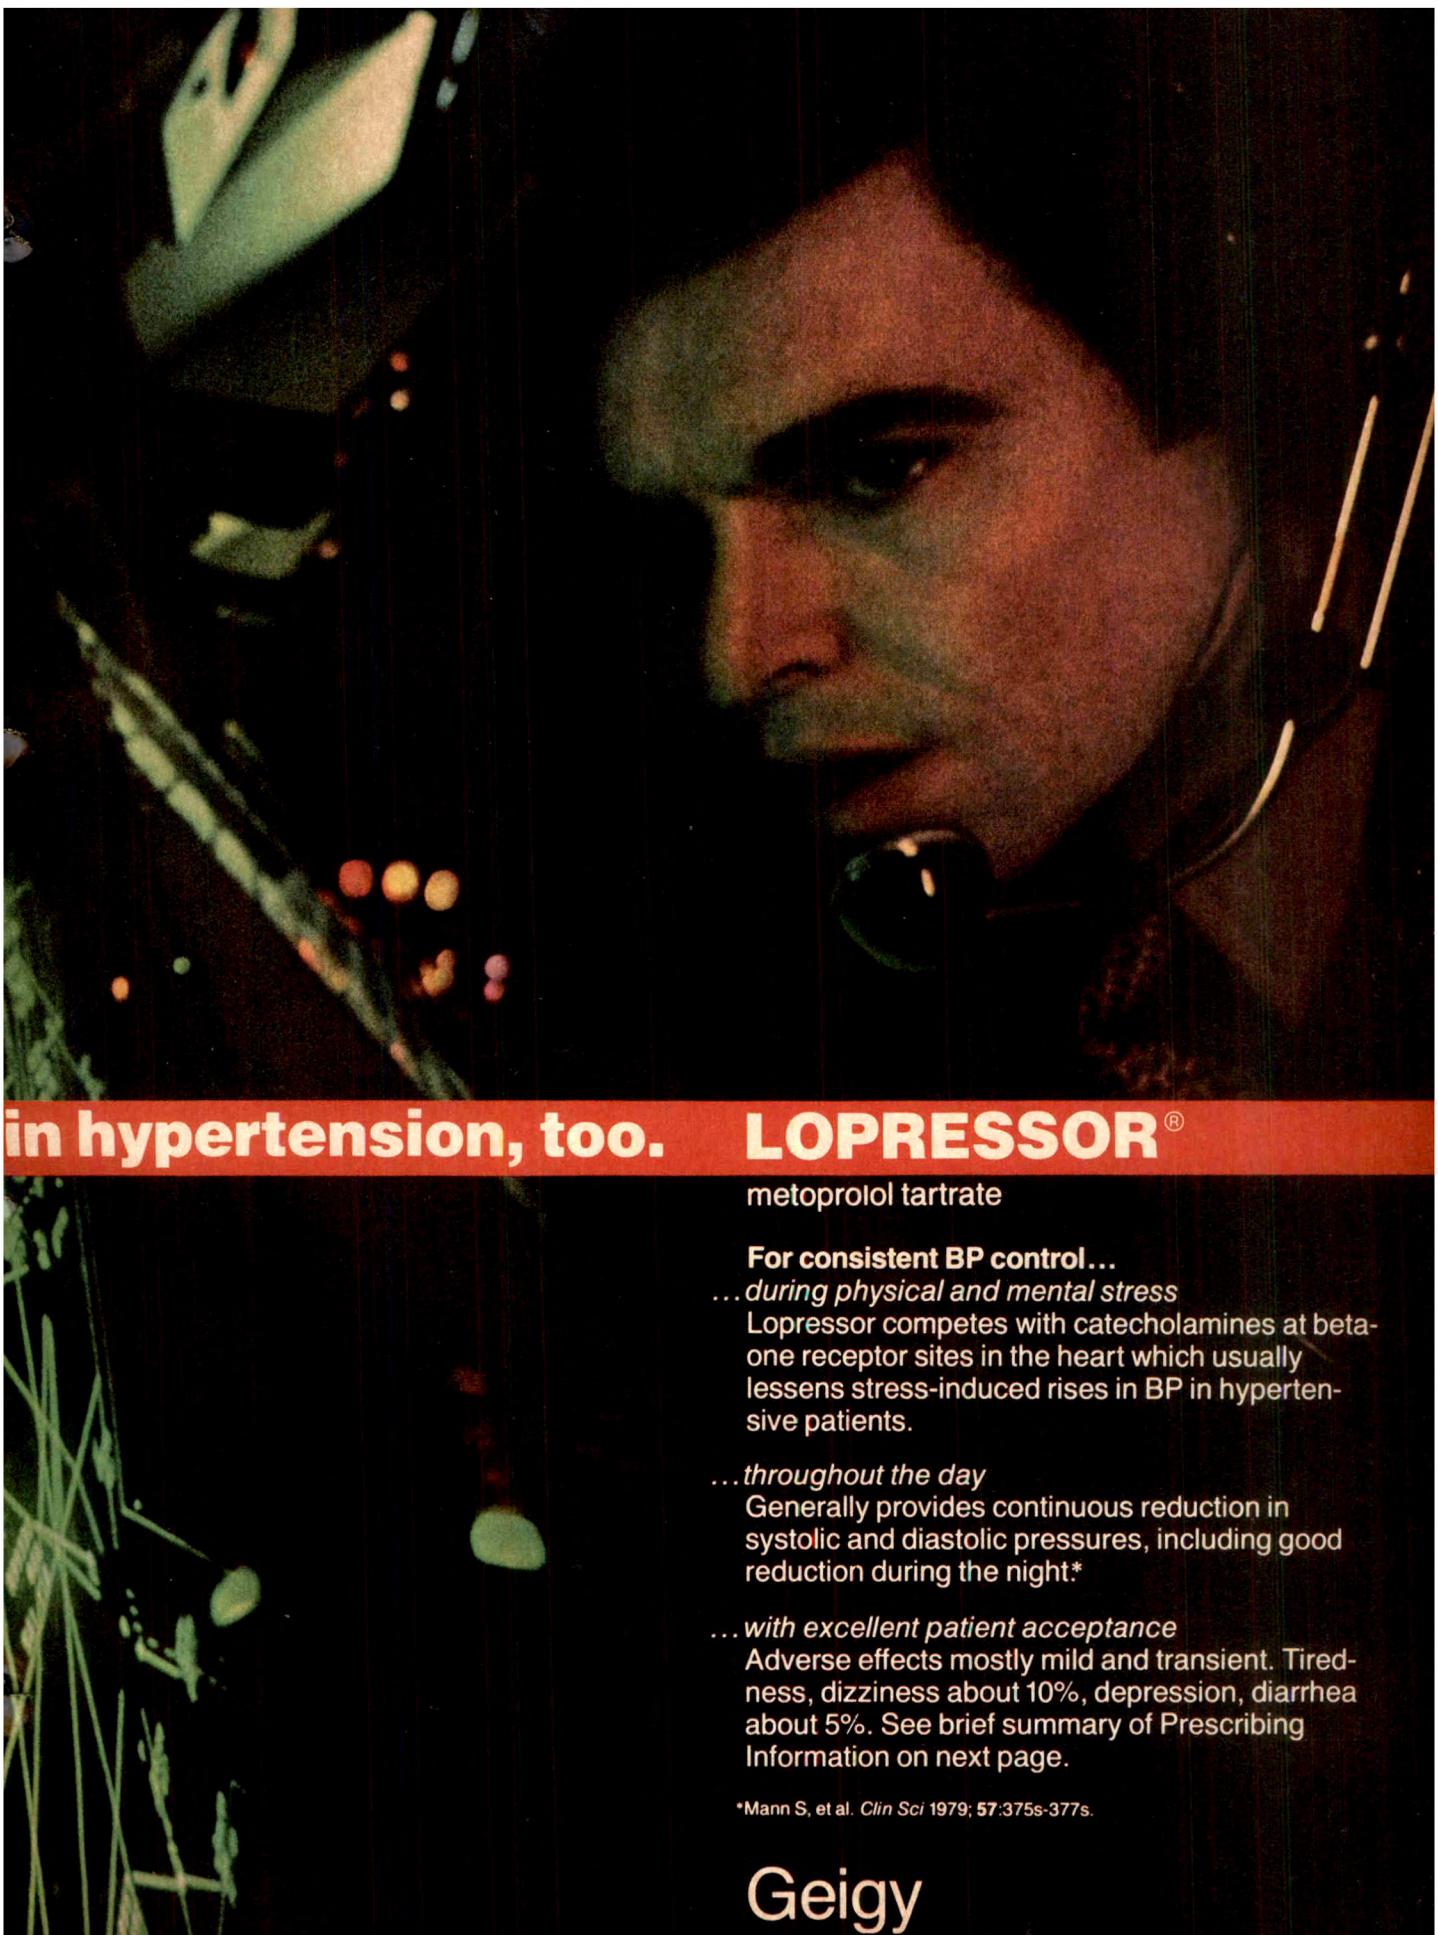
Consistent control counts..



in hypertension, too. LOPRESSOR®

metoprolol tartrate

For consistent BP control...

...during physical and mental stress
Lopressor competes with catecholamines at beta-one receptor sites in the heart which usually lessens stress-induced rises in BP in hypertensive patients.

...throughout the day
Generally provides continuous reduction in systolic and diastolic pressures, including good reduction during the night.*

...with excellent patient acceptance
Adverse effects mostly mild and transient. Tiredness, dizziness about 10%, depression, diarrhea about 5%. See brief summary of Prescribing Information on next page.

*Mann S, et al. *Clin Sci* 1979; **57**:375s-377s.

Geigy

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent	Tablets of 50 mg Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.
Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).
Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.
In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.
Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.
Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute, a $beta_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**
Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.
Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.
Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.
Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.
Precautions Impaired Hepatic or Renal Function: The drug should be used with caution in patients with impaired hepatic or renal function.
Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.
Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.
Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.
Usage in Children: Safety and effectiveness in children have not been established.
Adverse Reactions Most adverse effects have been mild and transient.
Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.
Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**
Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**
Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.
Allergic: Pruritus has occurred in less than 1 of 100 patients.
Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients. The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.
Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.
Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.
Cardiovascular: Intensification of AV block (see **Contraindications**).
Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.
Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.
Miscellaneous: Reversible alopecia.
Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.
Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta, selectivity diminishes as dosage of Lopressor is increased.
This drug should be stored at controlled room temperature and protected from moisture.
How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.
Store at controlled room temperature and protect from moisture.
Dispense in tight, light-resistant container (USP).

Coronary Hemodynamic Effects of Angiotensin Inhibition By Captopril and Teprotide in Patients With Congestive Heart Failure

JONATHAN L. HALPERIN, MD, DAVID P. FAXON, MD, MARK A. CREAGER, MD, THEODORE A. BASS, MD, CAROLINE D. MELIDOSSIAN, RN, HARALAMBOS GAVRAS, MD, and THOMAS J. RYAN, MD

The coronary hemodynamic effects of vasodilator therapy with angiotensin-converting enzyme inhibitors (captopril and teprotide) were studied in 11 patients with ischemic heart disease and severe congestive heart failure (CHF). Over 2 hours, systemic vascular resistance was reduced from 2,408 ± 240 to 1,715 ± 170 dynes·s·cm^{-5} ($p < 0.001$), and cardiac output improved 18%, resulting in lower arterial pressure (101 ± 8 to 86 ± 5 mm Hg, $p < 0.001$) and left ventricular filling pressure (30 ± 2 to 21 ± 2 mm Hg, $p < 0.001$). Coronary sinus thermodilution blood flow paralleled perfusion pressure but did not significantly vary overall (160 ± 20 to 133 ± 12 ml/min, difference not significant [NS]). Coronary vascular resistance was unchanged. Although the left ventricular stroke work index rose slightly (37.7 ± 8.8 to 41.3 ± 7.9 g·m/m^2, $p < 0.05$), there was no change in the coronary arteriovenous oxygen content difference (10.8 ± 1.0 to 10.4 ± 1.0 ml/100 ml, NS) or calculated myocardial oxygen consumption (16.4 ± 1.9 to 13.9 ± 1.6 ml/min, NS). The heart rate-systolic blood pressure product declined significantly during this period (8,824 ± 703 to 7,087 ± 514 beats·mm Hg, $p < 0.02$); this relief of cardiac effort was a function of the pretreatment plasma renin activity. A derived index of external myocardial efficiency improved 37% (19 ± 3 to 26 ± 6, $p < 0.05$), reflecting greater left ventricular work without increased oxygen demand.

Enhancement of myocardial performance after converting enzyme inhibition appears dependent on reduction of angiotensin-mediated ventricular afterload and preload. The lack of coronary vasomotor effects in patients with advanced ischemic cardiomyopathy may reflect limited coronary vascular reserve. Improvement of heart failure in these patients developed without evidence of myocardial ischemia, since balance was maintained between oxygen supply and demand.

Angiotensin-converting enzyme inhibitors lessen systemic vascular resistance and improve cardiac function in patients with CHF, yet the effects of this form of therapy upon cardiac perfusion and metabolism are mainly unknown.[1–5] Under normal circumstances resistance to coronary flow is regulated mainly by myocardial oxygen requirements, but coronary vessels also respond to stimulation of adrenergic and cholinergic receptors and to humoral mechanisms such as the renin-angiotensin system.[6,7] Obstructive coronary heart disease and ventricular dysfunction further influence the distribution of blood flow within the cardiac musculature. Consequently, the responses of the coronary circulation to ischemic myocardial failure are particularly difficult to define.

We examined coronary hemodynamics and myocardial energetics in a group of patients with severe CHF due to coronary heart disease during therapy with 2 distinct converting enzyme inhibitors (captopril and

teprotide). The purpose of the study was to help define the impact of the renin-angiotensin system on coronary vascular tone in patients with ischemic cardiomyopathy and shed light on the myocardial energetic consequences of vasodilator therapy in this disorder.

Methods

Study patients: Eleven patients with signs and symptoms of severe CHF in New York Heart Association functional classes III and IV were studied. All had angiographic evidence of advanced multivessel coronary artery disease or documented previous myocardial infarction. Seven of these patients had angina pectoris. None had had clinically apparent infarction within 6 months of study or had predominant valvular disease. Eight patients were male and 3 were female; their ages ranged from 52 to 75 years (average 63). The duration of cardiac failure ranged from 5 months to 14 years (average 3.7 years).

Catheterization procedures: The experiment had the approval of the Institutional Review Board for Human Research, and each patient gave informed consent. Subjects were maintained in the hospital on an 86 mEq/day sodium diet for 3 days before study. Digitalis, diuretics, and all medications other than clinically necessary antiarrhythmic agents were withheld for 24 hours before the hemodynamic studies. With patients in the recumbent, postabsorptive state and without premedication, 18-g polyethylene radial arterial cannulas were placed. Each patient underwent right heart catheterization with a 7Fr Swan-Ganz catheter (Instrumentation Laboratories), and coronary sinus catheterization was performed with an 8Fr Ganz thermodilution catheter (USCI Division, C.R. Bard). These catheters were introduced through antecubital veins and positioned using fluoroscopy. Periodic injections of small volumes of radioopaque contrast medium confirmed the location of the coronary sinus catheter during the studies. Pressures were measured using Bentley model 508 strain-gauge transducers and recorded on a direct-writing Hewlett-Packard multigraph. Mean pressures were obtained by electronic integration with zero-reference at the level of the mid-axillary line. Heart rate was determined from the simultaneous electrocardiographic signal. Cardiac output was quantified by thermodilution, using an Instrumentation Laboratories model 601 cardiac output computer and averaging at least 3 replicate determinations varying less than 10%. Coronary sinus blood flow was measured by the thermodilution technique, using a Wheatstone bridge (Wilton-Webster Laboratories, Altadena, California) and recorded as described by Ganz et al.[8] Whole blood oxygen saturation was measured with a Beckman spectrophotometer according to the method of Gordy and Drabkin,[9] and corrected for the oxygen-carrying capacity of hemoglobin to derive volumetric oxygen content. Lactate content was determined by the method of Friedland and Dietrich.[10] Plasma renin activity was quantified in systemic venous blood by radioimmunoassay of angiotensin I generation.[11]

Measurements before and after captopril or teprotide: Systemic hemodynamic data were collected until 3 successive determinations 15 minutes apart demonstrated homeostasis. Coronary sinus blood flow measurements were made simultaneously with measurements of cardiac output, systemic blood pressure, pulmonary capillary wedge pressure, right atrial pressure, and heart rate. Coronary sinus and arterial blood were sampled simultaneously for determinations of oxygen and lactate contents immediately after each measurement of coronary sinus flow. Venous blood was taken for plasma renin activity and norepinephrine concentration just before drug administration. Five patients were given teprotide, 1 mg/kg as an intravenous injection, and 6 patients received captopril, 100 mg orally (Squibb Institute of Medical Research, Princeton, New Jersey). Hemodynamic data were collected at 15, 30, 45, and 60 minutes thereafter in patients given teprotide, and at 30, 60, 90, and 120 minutes after captopril administration. Blood for oxygen content and lactate

AVO_2 df = coronary arteriovenous oxygen content difference; CSBF = coronary sinus blood flow; CVR = coronary vascular resistance; EME = external myocardial efficiency; MVO_2 = myocardial oxygen consumption; RPP = rate-pressure index.

concentration was drawn at the time of hemodynamic measurements, and blood for plasma renin activity was taken 60 and 120 minutes after administration of teprotide and captopril, respectively.

Hemodynamic indexes were derived from pressure, flow, and oxygen content values according to the formulas presented in the Appendix. Coronary sinus flow was derived from the change in the temperature of coronary sinus blood during infusion of 5% dextrose in water at 20°C at a rate of 50 ml/min, as detected by thermistors mounted on the coronary sinus catheter. The relative densities and specific heats of coronary sinus blood and indicator solution of dextrose required a constant correction factor of 1.08. Total coronary resistance was calculated as the ratio of arteriovenous driving pressure to coronary sinus flow. Myocardial oxygen consumption was evaluated as the product of blood flow and oxygen extraction. External myocardial efficiency was calculated to express the amount of cardiac work performed per unit of oxygen consumed.

Statistical analysis: Systemic hemodynamic measurements were averaged over the control period and over the hour of peak systemic vasodilatory effect, determined from the change in systemic vascular resistance. Data before and after converting enzyme inhibition were compared and evaluated by the paired Student's *t* test and expressed as mean ± standard error of the mean. The Pearson product-moment correlation coefficient was computed for effects along selected parameters. Statistical significance was accepted at the 95% confidence level ($p < 0.05$).

Results

Plasma renin activity: In all 11 cases, chronic CHF was attributed to coronary heart disease. The population remained heterogeneous with respect to basal plasma renin activities, which ranged from 3.9 to 68.0 ng/ml/h. Renin activity increased in all cases, but increased the most in patients with the highest baseline levels. The individual and group results are presented in Tables I and II.

Systemic vasodilatation: Pretreatment plasma renin activity predicted the degree of systemic vasodilatation after drug administration ($r = -0.604$; $p < 0.05$). Systemic vascular resistance was consistently lower after converting enzyme inhibition than during the control period. On average, the mean arterial pressure decreased 15 percent as the cardiac index improved 18 percent. Mean pulmonary capillary wedge pressure fell 30 percent, but generally remained well above the normal range after treatment with angiotensin inhibitors. Mean right atrial pressure did not fall significantly

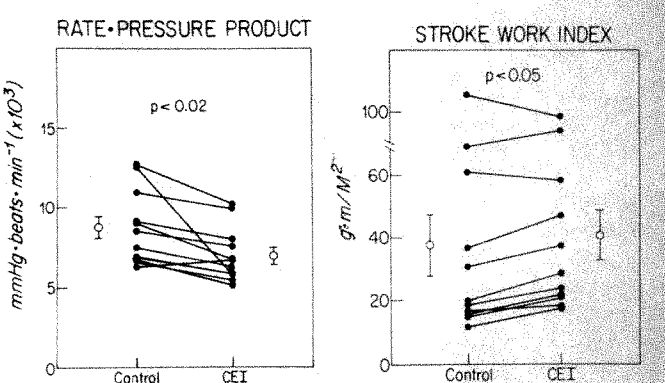

FIGURE 1. Left ventricular stroke-work index (**right**) and heart rate-systolic blood pressure product (**left**) in each patient before and after converting enzyme inhibition (CEI) (mean ± standard error of the mean [SEM]).

during short-term observation. The heart rate slowed slightly. The index of left ventricular stroke work increased in 9 of 11 patients (Fig. 1). Simultaneously, the product of the heart rate and systolic blood pressure (an index of cardiac effort) declined an average of 19 percent. The change in rate-pressure product reflected the decrease in systemic vascular resistance and was related to baseline plasma renin activity ($r = -0.769$; $p < 0.01$).

Coronary hemodynamics: During the period of drug action, there was no significant change in coronary sinus blood flow (Fig. 2). In 8 patients, flow decreased; the reduction in coronary venous flow was related to the decrease in perfusion pressure ($r = 0.750$; $p < 0.01$). Calculated total coronary resistance was also unchanged despite substantial systemic vasodilatation. Changes in coronary sinus blood flow paralleled reductions in blood pressure. The transmyocardial diastolic pressure gradient (calculated as the difference between diastolic systemic arterial pressure and pulmonary capillary wedge pressure) was unchanged during converting enzyme inhibition.

Myocardial function and metabolism: Coronary sinus blood oxygen content initially averaged 3.9 ± 0.2 ml/100 ml. There was no shift in the coronary arteriovenous oxygen difference after administration of the converting enzyme inhibitors. Myocardial oxygen consumption was not changed significantly (16.4 ± 1.9 to 13.9 ± 1.6 ml/min, $p < 0.20$). Values decreased in 8 subjects, however, and parallelled the change in the rate- pressure product ($r = 0.613$; $p < 0.05$). Enhanced stroke work without change in oxygen uptake indicates improvement in the metabolic efficiency of the heart (Fig. 3). The calculated index of external myocardial efficiency improved from 19 ± 3 to 26 ± 6% ($p < 0.05$), and substantial increases occurred in most patients. In accord with these findings, no significant increment in myocardial lactate production developed even at reduced rates of myocardial perfusion (20 ± 13 to 13 ± 13%, $p < 0.50$).

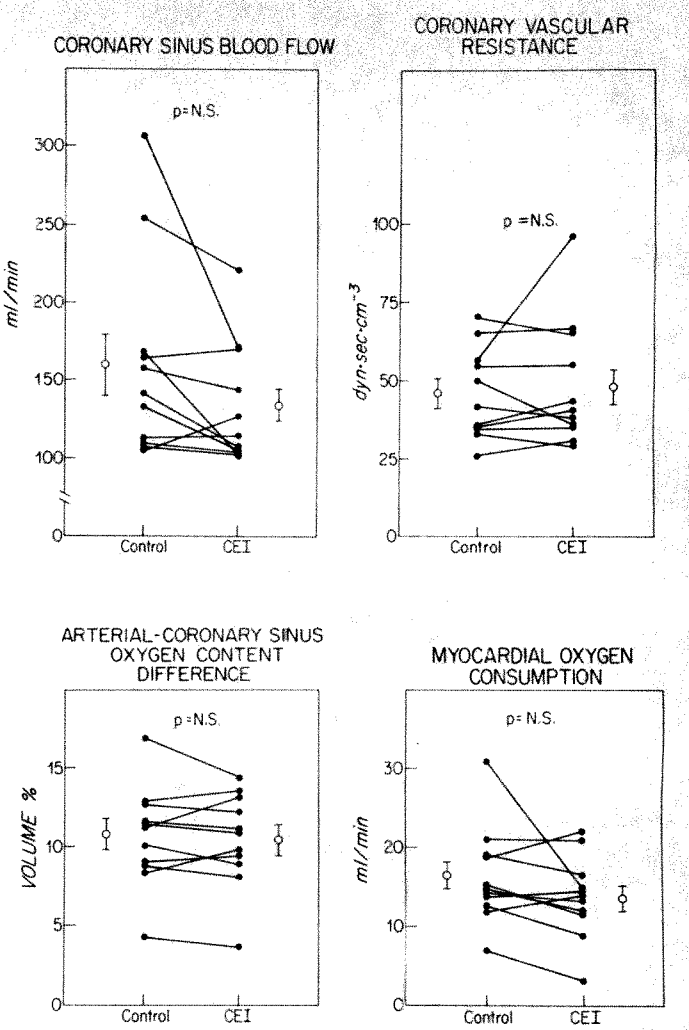

FIGURE 2. Coronary hemodynamic response to angiotensin inhibition (CEI). Coronary sinus blood flow, coronary vascular resistance, coronary arteriovenous oxygen content difference, and myocardial oxygen consumption are given for each subject, along with the mean ± SEM.

Discussion

Role of renin-angiotensin system: In patients with CHF, regional tissue perfusion is regulated selectively by a variety of vasoconstrictor mechanisms. Collectively, systemic vasoconstriction generates resistance to left ventricular ejection, increasing intramyocardial tension during systole. The afterload imposed by aortic impedance represents a principal determinant of myocardial oxygen consumption. In the patients with chronic coronary heart disease described herein, the decrease in peripheral resistance during therapy with angiotensin converting enzyme inhibitors was related to the baseline plasma renin activity. Inhibition of the vasoconstrictor properties of angiotensin II is thus implicated, although other neurohumoral actions may contribute to the effects of teprotide and captopril.[12] Both angiotensin I and angiotensin II produce coronary vasoconstriction in anesthetized dogs. The increase in coronary vascular resistance after administration of angiotensin I is inhibited by teprotide.[13] In renin-stimulated canine models, converting enzyme inhibitors increase coronary blood flow.[14,15] Recently, we demonstrated that converting enzyme inhibition with teprotide increases coronary sinus blood flow in normal human subjects without suppressed plasma renin activities.[16] A role for the renin-angiotensin system in regulating coronary vasomotor activity is suggested by these observations.

Effect of angiotensin inhibition on coronary hemodynamics: In our patients with advanced ischemic heart disease, pretreatment values of coronary sinus blood flow ranged nearly threefold. There was no net change in the coronary sinus flow measurements after angiotensin inhibition. In several cases, however, flow rates diminished, and blood pressure decreased the most in these cases. It would seem from the constancy of the calculated coronary resistance that no vasodilatation or vasoconstriction developed in the coronary bed. This relative coronary vasomotor inactivity may reflect the limitation of coronary vascular reserve in

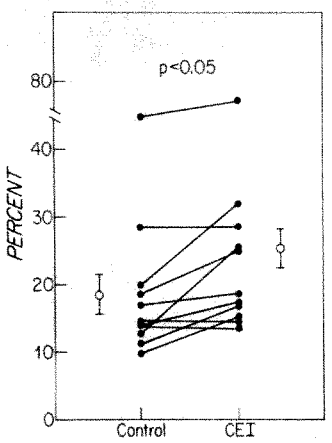

FIGURE 3. Calculated index of external myocardial efficiency for each patient before and after converting enzyme inhibition (CEI) (mean ± SEM).

ischemic heart disease.[17] Resistance to myocardial blood flow derives from several components: (1) the fixed resistance imposed by the vascular walls and blood constituents; (2) the cyclic effects of intramyocardial compression; and (3) the regulatory resistance due to constriction of arterioles.[18] In the patients we studied, resistance at the level of the epicardial coronary arteries was probably high and relatively fixed as a result of obstructive atherosclerotic disease. In response to elevated basal resistance, compensatory arteriolar vasodilatation may develop at the expense of coronary vascular reserve. Extravascular coronary resistance varies directly with changes in intramyocardial compressive forces, which are related to afterload, preload, and contractility. Flow through coronary collateral channels is subject to other factors, yet perfusion pressure is probably critical. The fact that calculated coronary resistance was constant in our study implies a balance between palliative effects on wall tension and reduced arteriovenous driving pressure across the coronary vascular bed. Excessive ventricular afterload and preload may provide the dominant metabolic stimulus to the preservation of coronary blood flow in patients with heart failure due to coronary heart disease. We have not measured total myocardial perfusion, and our results are subject to the limitations of the coronary sinus thermodilution technique.[8] Even if total blood flow were unchanged, angiotensin inhibition might modify its distribution within cardiac muscle toward or away from ischemic zones.

Effect on myocardial oxygen consumption: The coronary circulation is subject to autoregulation by which resistance to coronary blood flow is dictated predominantly by myocardial oxygen demands.[19] Even under physiologic conditions, myocardial oxygen extraction is high, so the oxygen saturation of coronary venous blood normally averages only 20 to 30 percent. The efficiency with which oxygen is utilized normally remains relatively fixed, and increases in myocardial oxygen requirements must therefore be met by corresponding increments in coronary blood flow. Factors which determine myocardial oxygen requirements, particularly ventricular wall tension (a product of intramyocardial pressure and chamber dimensions), heart rate, and the contractile state of the myocardium, ultimately modulate coronary blood flow. Very low values of coronary venous oxygen content were recorded in our patients with ischemic cardiomyopathy, indicating nearly maximum myocardial extraction of the arterial oxygen content. Calculated myocardial oxygen consumption was not significantly lowered during vasodilator therapy with angiotensin-converting enzyme inhibitors despite the decrease in rate-pressure product. Since left ventricular filling pressure and systemic vascular resistance decreased, it seems reasonable that both chamber distention and outlet impedance were reduced. An inotropic action of teprotide or captopril cannot be excluded, and this could explain the discrepancy between the rate-pressure product and myocardial oxygen consumption. In addition, this estimate of oxygen consumption conceals regional differences in oxygen employment within the myocardium.

Effect on myocardial efficiency: Clinical implications: While myocardial oxygen consumption did not change, relief of congestive heart failure allowed greater stroke work to be generated from a fixed quantity of oxygen. The percent change in external myocardial efficiency was a function of that in plasma renin activity after converting enzyme inhibition. This relation between efficient cardiac oxygen utilization and the renin-angiotensin system may be based on reduction of ventricular afterload and preload. The clinical implication is that heart failure may be improved by angiotensin inhibition without adversely affecting myocardial energetics in patients with coronary heart disease. Accordingly, our patients seem to have enjoyed functional benefit without exacerbation of angina. Each patient studied had advanced coronary heart disease and ischemic cardiomyopathy, and our results may not be applicable to patients with other forms of cardiomyopathy or to those with valvular heart disease.

In conclusion, angiotensin-converting enzyme inhibitors produce systemic vasodilatation and improve cardiac function in patients with CHF due to ischemic disease. Coronary sinus blood flow and myocardial oxygen extraction are not altered despite a decrease in the rate-pressure product. Angiotensin-converting enzyme inhibition exerts no coronary vasomotor effect in advanced ischemic cardiomyopathy, either as a consequence of limited coronary vascular reserve, a lack of angiotensin-mediated coronary vasoconstriction, or the minimal overall change in myocardial metabolic demands during this form of vasodilator therapy. Nevertheless, angiotensin inhibition improves myocardial efficiency in ischemic cardiomyopathy and appears useful in the management of patients with this disorder.

Accuracy of Cardiac Output, Oxygen Uptake, and Arteriovenous Oxygen Difference at Rest, During Exercise, and After Vasodilator Therapy in Patients With Severe, Chronic Heart Failure

STANLEY A. RUBIN, MD, DEIRDRE SIEMIENCZUK, RN, MARK D. NATHAN, MD, JOANN PRAUSE, MS, and H. J. C. SWAN, MD, PhD

Measurement of cardiac output, arteriovenous oxygen difference, and oxygen uptake in patients with heart failure may be subject to technical and biologic inaccuracies. We measured these 3 variables in 16 patients with chronic heart failure at rest and during exercise. When cardiac output was measured by thermodilution and compared with values calculated by the Fick principle, there was a significant correlation at rest ($r = 0.91$, $p < 0.001$) and at exercise ($r = 0.93$, $p < 0.001$). When the arteriovenous oxygen difference was measured by spectrophotometry of arterial and mixed venous samples and compared with values calculated by the Fick principle, there was a significant correlation at rest ($r = 0.80$, $p < 0.01$) and at exercise ($r = 0.76$, $p < 0.01$). When oxygen uptake was measured from expired gas analysis and compared with values calculated by the Fick principle, there was a significant correlation at rest ($r = 0.84$, $p < 0.01$) and at exercise ($r = 0.94$, $p < 0.001$). In addition, 10 patients received vasodilator treatment which increased cardiac output and decreased the arteriovenous oxygen difference at rest and exercise. There was no significant difference between measured and calculated values for the 3 variables under those additional conditions. It is concluded that despite technical and biologic difficulties, cardiac output, arteriovenous oxygen difference, and oxygen uptake, when calculated from Fick's principle, yield results equivalent to direct measurement.

Renewed interest in the exercise physiology of patients with severe heart failure has been spurred by the relative safety of procedures such as invasive hemodynamics and exercise, and by the desire to evaluate responses to new therapies. Measurement of cardiac transport and gas exchange involves 3 variables—arteriovenous oxygen difference, cardiac output, and oxygen uptake—which are inextricably linked during the steady state. Innumerable recent reports have employed different techniques to measure the 3 variables in Fick's equation. It has not been possible to compare the results of these reports because studies of reproducibility correlating different techniques are not available. Physiologic changes and pharmacologic interventions in patients with heart failure impose technical difficulties or biological uncertainties which may void the assumptions of Fick's principle, on which such measurements are based. We examined the interrelation among these 3 variables and assessed individual patients during exercise and during arteriolar vasodilator treatment to define the accuracy of these data.

Methods

Patients: Sixteen patients with chronic heart failure, with severe left ventricular dysfunction secondary to idiopathic cardiomyopathy or ischemic heart disease, were studied to assess cardiovascular transport. These patients had been referred to our medical center because of intractable symptoms of heart failure. Some were studied as part of advanced diagnostic testing, while others were part of experimental drug protocols. Where appropriate, these protocols were approved by the Human Subjects Committee of this institution. In-

TABLE I Supine Resting Hemodynamic Variables*

Heart rate (min^{-1})	82 ± 16
Mean arterial pressure (mm Hg)	87 ± 14
Mean pulmonary arterial pressure (mm Hg)	40 ± 8
Pulmonary capillary pressure (mm Hg)	26 ± 6
Right atrial pressure (mm Hg)	14 ± 6
Cardiac index (liters/min·m^2)	2.0 ± 0.5
Left ventricular ejection fraction	0.22 ± 0.07

* Values are mean ± standard deviation for 16 patients.

formed written consent was obtained for all procedures. Thirteen patients were men and 3 were women, and their mean age was 58 years (range 33 to 78). Each patient had severe symptoms of exercise intolerance due to fatigue, dyspnea, or both (New York Heart Association class III).[1] Supine resting hemodynamics and ejection fraction averages (Table I) showed severe abnormalities of left ventricular function in each patient and abnormalities of right ventricular function in some patients.

Measurement and calculation of arteriovenous oxygen difference: The arteriovenous oxygen difference ($AV\text{-}O_2$; ml/dl; standard temperature and pressure, dry [STPD]) was measured as the difference between the oxygen content of arterial and mixed venous blood (Ca-Cv) and for comparison was calculated as the quotient of oxygen uptake divided by cardiac output ($\dot{V}O_2/CO$) (for details of these methods, see later). Aliquots of arterial and mixed venous blood were simultaneously analyzed in a gas tension/pH analyzer (model 175, Corning Instruments, Medfield, Massachusetts) and in a quadruple beam spectrophotometer (IL 282, Instrumentation Laboratory, Cambridge, Massachusetts). The accuracy of the blood gas analyzer is ±1.0 torr for oxygen and carbon dioxide tensions and ±0.01 for pH. The accuracy of the spectrophotometer is ±0.01 for absolute oxygen saturation fraction and ±0.3 g/dl for hemoglobin. Oxygen saturation was measured directly by the spectrophotometer at 37°C.[2] Oxygen contents (Ca and Cv) were calculated as follows: $(Hgb \times S \times 1.34) + (PO_2 \times 0.003)$, where Hgb is the hemoglobin concentration (g/dl), 1.34 is the empirical value of oxygen capacity of a gram of hemoglobin, S is the oxygen saturation expressed as a fraction (determined by the spectrophotometer), and PO_2 is the oxygen tension (determined by the blood gas analyzer). The first component in the equation represents the blood oxygen carried by hemoglobin; the second component represents the blood oxygen dissolved in solution.

Measurement and calculation of cardiac output: Cardiac output (CO, liters/min) was measured by right heart thermodilution and for comparison was calculated as the quotient of oxygen consumption divided by the arteriovenous oxygen difference ($\dot{V}O_2/AV\text{-}O_2$) (for details of $\dot{V}O_2$, see later). For thermodilution, 10 ml of iced 5% dextrose in water solution was rapidly injected into the right atrial part of the Swan-Ganz catheter while the temperature transient was detected by the thermistor in the pulmonary artery.[3] Calculation of cardiac output was performed on-line by a cardiac output computer (model 9520A, Edwards Laboratories, Santa Ana, California). The variation among quadruple cardiac outputs obtained while the patients were at rest was less than 10%.

Measurement and calculation of oxygen uptake: Oxygen uptake ($\dot{V}O_2$; ml/min; STPD) was measured by the open-circuit technique (collection of expired gas) and for comparison was calculated as the product of cardiac output and arteriovenous oxygen difference ($CO \times AV\text{-}O_2$). For the open-circuit technique, patients breathed room air through a mouthpiece connected to a low resistance two-way valve (modified Otis-McKerrow, Collins, Cambridge, Massachusetts), and expired gas was directed through a short length of tubing, and then through a low resistance three-way valve (model 7210, Collins) into a latex meteorologic balloon (model 80 MRL, Kaysam, Piscataway, New Jersey). The expired gas in the balloons was measured for fractional oxygen (F_EO_2) and carbon dioxide (F_ECO_2) concentrations by a medical mass spectrometer (model MGA 1100, Perkin Elmer, Pomona, California) calibrated with gravimetrically analyzed gases. Expired minute ventilation ($\dot{V}_E$) was determined by timing the gas collection and measuring the collected volume in a water-seal gasometer (120 liter gasometer, Collins). Volumes in the gasometer were corrected from ambient temperature and pressure, saturated [ATPS] to STPD. Oxygen uptake was calculated as follows: $\dot{V}O_2 = \dot{V}_E [0.265 \times (1.00 - F_EO_2 - F_ECO_2) - F_EO_2]$. This equation corrects for the difference between inspired and expired gas volumes by assuming that inert gas volumes are constant. The accuracy of the mass spectrometer is ±0.1% for oxygen absolute and ±0.01% for carbon dioxide absolute. The accuracy of the gasometer is ±70 ml.

Exercise protocol: Patients performed incremental exercise on a weight-flywheel cycle ergometer.[4] Stages were 3 minutes in duration beginning with unloaded pedalling—that is, only work required to turn the unloaded flywheel—and increased by 160 kpm/min (25 W) per stage. Patients exercised to their symptom-limited maximum as determined by the patients themselves as the point of intolerable dyspnea, generalized fatigue, or both, or leg fatigue. The final stage of exercise was frequently prolonged to 4 to 6 minutes to allow completion of measurements. In the patients reported here, peak work load ranged from unloaded pedalling (0 load) in severely disabled patient up to 480 kpm/min (75 W).

Drug protocol: An arteriolar vasodilator was administered orally in incremental doses so as to increase cardiac output at least 20% over control values at rest and exercise. Hydralazine was administered every 6 hours with a range of peak doses from 50 to 150 mg every 6 hours. Minoxidil was administered every 12 hours with a range of peak doses from 5 to 20 mg every 12 hours. Doses were administered over a range of 36 to 72 hours before the patients were retested. Patients were restudied 2 hours after a drug dose. All patients were also taking digoxin and furosemide, and these were continued throughout the study.

Measurement protocol: Measurements were made at 2 conditions (rest and peak exercise) and at 2 treatments (control and drug). Sixteen patients had measurements at rest and peak exercise during control treatment. Ten of these patients also had measurements at rest and peak exercise during drug treatment. We made measurements at rest after the patients had been sitting on the bicycle for 10 minutes, and used the following protocol. After the first thermodilution cardiac output determination was completed, a 3 minute gas collection was begun simultaneously with a second thermodilution cardiac output determination. At the end of the second cardiac output determination, arterial and duplicate mixed venous blood samples were obtained for oxygen content. This blood sampling took approximately 1 minute during the middle of the gas collection. The end of the third thermodilution cardiac output determination approximately coincided with the end of the gas collection, and then a fourth cardiac output determination was performed. The sampling regimen was slightly modified during exercise so as to decrease the period of the measurements during exercise. A 60 to 90 second gas collection was performed beginning with the second thermodilution cardiac output determination, and gas

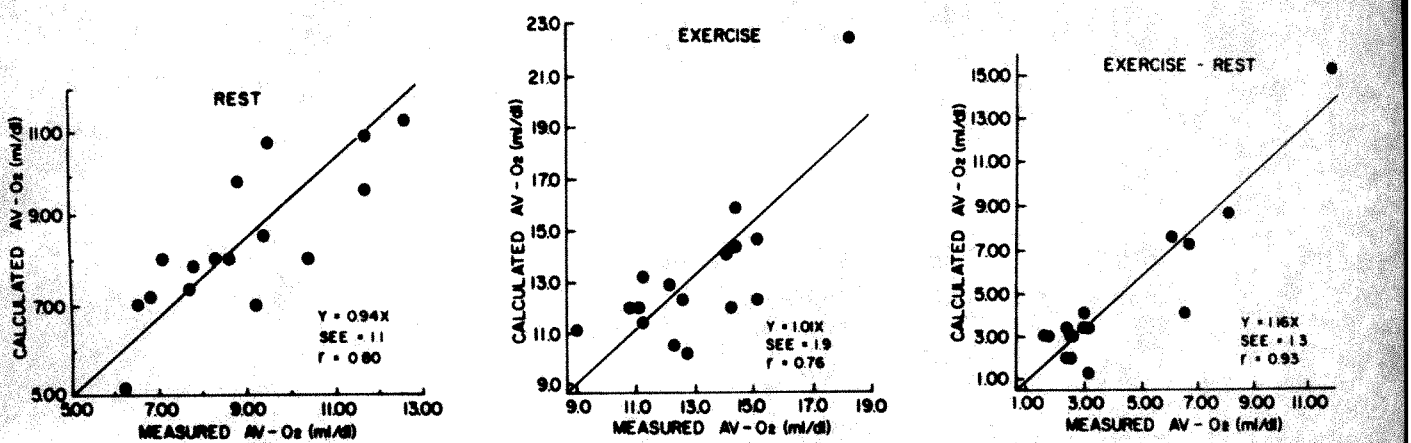

FIGURE 1. Measured compared with calculated arteriovenous oxygen difference ($AV\text{-}O_2$). Appearing in each panel is the regression line (constrained to pass through the zero-zero intercept), the regression equation, the standard error of the estimate (SEE), and the correlation coefficient (r). Each correlation was very significant ($p < 0.01$). Each regression line slope coefficient was not different from a slope of 1.0. **Left panel,** comparison at rest. **Center panel,** comparison during exercise. **Right panel,** comparison of differences between rest and exercise. An exception was found in the statistical testing of slope (see text).

collection continued with the blood sampling. A third cardiac output determination was performed coincident with the end of gas sampling.

Data analysis: No datum was discarded in any patient. The investigators were satisfied that all measurements were obtained accurately. The measured variables of arteriovenous oxygen difference, cardiac output, and oxygen uptake were compared with the calculated variables by regression analysis[5] at rest, during exercise, and for changes between rest and exercise. There was no a priori reason to believe that the calculated variables were systematically different from the measured variables. Therefore, the regression lines were constrained to pass through a zero intercept. The deviation of the slope of the regression line from 1.0 measures the extent to which the measured and calculated variables disagree. In addition, the slope of the line was tested to determine whether or not it was statistically different from a slope of 1.00. The zero order correlation coefficient was obtained for all regressions and measures the linear dependence between measured and calculated variables. The standard error of the estimate provides a measure of the fit of the data to the regression line.

We also recognized another question appropriate for statistical testing: Is there equality of the data sets for measured and calculated data under both control and vasodilator therapy? Analysis of variance was used to compare the measured and calculated data under the control and vasodilator conditions. The statistical model utilized was a 3 factor analysis of variance with repeated measures on all factors.[6] The 2 levels of the first factor were the measured and calculated conditions, the 2 levels of the second factor were the presence and absence of vasodilator therapy, and the 2 levels of the third factor were the rest and exercise conditions. The levels of significance presented in the current study represent probabilities derived from a test of the main effect for the measured and calculated factor. Statistical significance was set at the 0.05 level ($p \leq 0.05$).

Results

The terms *measured* and *calculated*, as used herein, refer to our definitions as provided in the Methods section.

Arteriovenous oxygen difference (Fig. 1, Table II): The range of arteriovenous oxygen content difference during control therapy was from 6.2 to 18.4 ml/dl. Modest and significant ($p < 0.01$) correlation coefficients were found between measured and calculated values at rest ($r = 0.80$) and during exercise ($r = 0.76$) and for the change between rest and exercise ($r = 0.93$). The slope of the regression line was not different from a slope of 1.0 for rest and exercise conditions, but was different for the change between rest and exercise. For the 10 patients whose data were examined under 4 conditions, (control rest, control exercise, vasodilator rest, and va-

TABLE II Measured and Calculated Variables for Patients Treated With Vasodilators

	Measured				Calculated				
	CR	CE	VR	VE	CR	CE	VR	VE	p
$AV\text{-}O_2$ (ml/dl) (n = 10)	8.6 ± 1.8	13.8 ± 2.1	5.8 ± 1.1	11.6 ± 2.6	7.9 ± 1.6	13.5 ± 3.6	5.7 ± 0.9	11.7 ± 3.2	NS (>0.20)
CO (liters/min) (n = 10)	3.6 ± 1.1	4.9 ± 1.5	4.7 ± 0.7	5.9 ± 1.4	3.4 ± 1.1	4.8 ± 1.7	4.7 ± 0.9	6.0 ± 1.7	NS (>0.20)
VO_2 (ml/min) (n = 10)	273 ± 63	658 ± 249	267 ± 39	699 ± 255	296 ± 57	667 ± 217	269 ± 37	695 ± 250	NS (>0.20)

Values are mean ± standard deviation. $AV\text{-}O_2$ = arteriovenous oxygen difference; CE = control treatment during exercise; CO = cardiac output; CR = control treatment at rest; n = number of patients; NS = not significant; p = significance of difference between measured and calculated values. VE = vasodilator treatment during exercise; VO_2 = oxygen uptake; VR = vasodilator treatment at rest.

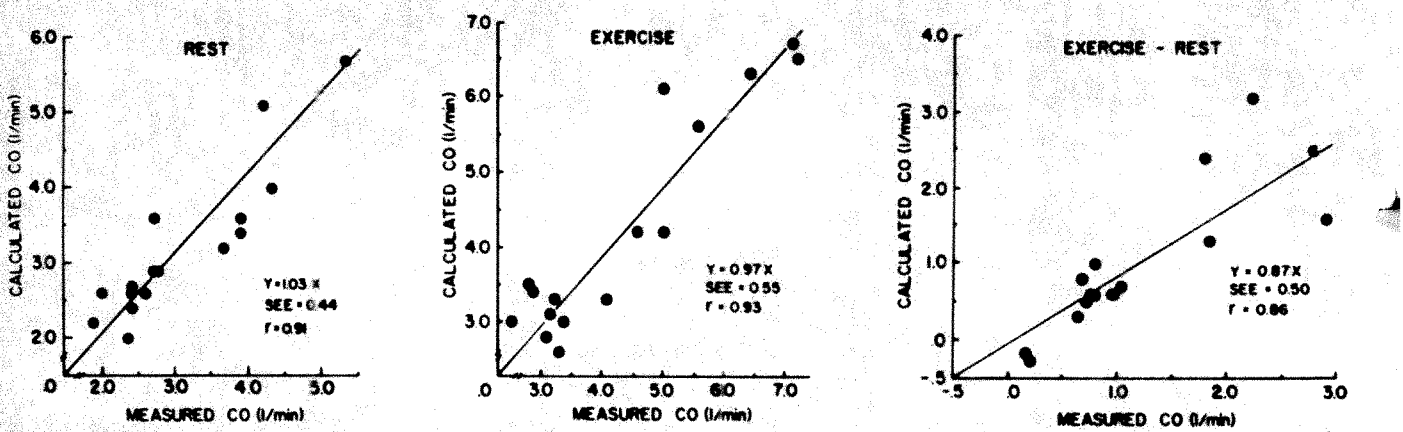

FIGURE 2. Measured compared with calculated cardiac output (CO). Data were analyzed by linear regression. Symbols, panel arrangement, and results of statistical testing are similar to those in Figure 1.

sodilator exercise), there was no significant difference between measured and calculated arteriovenous oxygen difference across the conditions.

Cardiac output (Fig. 2, Table II): The range of cardiac output during control therapy was 2.0 to 6.7 liters/min. High and significant ($p < 0.01$) correlation coefficients were found between measured and calculated values at rest ($r = 0.91$) and during exercise ($r = 0.93$) and for the change between rest and exercise ($r = 0.86$). The slopes of the regression lines under these conditions were not different from 1.0. For the 10 patients whose data were examined under 4 conditions (control rest, control exercise, vasodilator rest, and vasodilator exercise), there was no significant difference between measured and calculated cardiac output across the conditions.

Oxygen uptake (Fig. 3, Table II): The range of oxygen uptake during control therapy was 165 to 1,028 ml/min. High and significant ($p < 0.01$) correlation coefficients were found between measured and calculated values at rest ($r = 0.84$) and during exercise ($r = 0.94$) and for the change between rest and exercise ($r = 0.95$). The slopes of the regression lines under these conditions were not different from 1.0. For the 10 patients whose data were examined under 4 conditions (control rest, control exercise, vasodilator rest, and vasodilator exercise), there was no significant difference between measured and calculated oxygen uptake across the conditions.

Discussion

There is no single comprehensive report on the comparison of methods of measurement of cardiac output and gas exchange variables in patients with heart failure. Our report is unique because of the heart failure patient population, the rest and exercise conditions of the study, and the drug interventions used—all of which are expected to change the actual measured quantities and the time to steady-state values.

Comparison of methods of measurement: We measured the oxygen content of arterial and mixed venous blood by spectrophotometry, we measured cardiac output by thermodilution, and we measured oxygen uptake by analysis of expired gas. As a comparison, we applied Fick's principle as another method of measuring these 3 variables. The comparison between methods was performed in patients with severe chronic heart failure at rest, during maximum cycle ergometry, and again

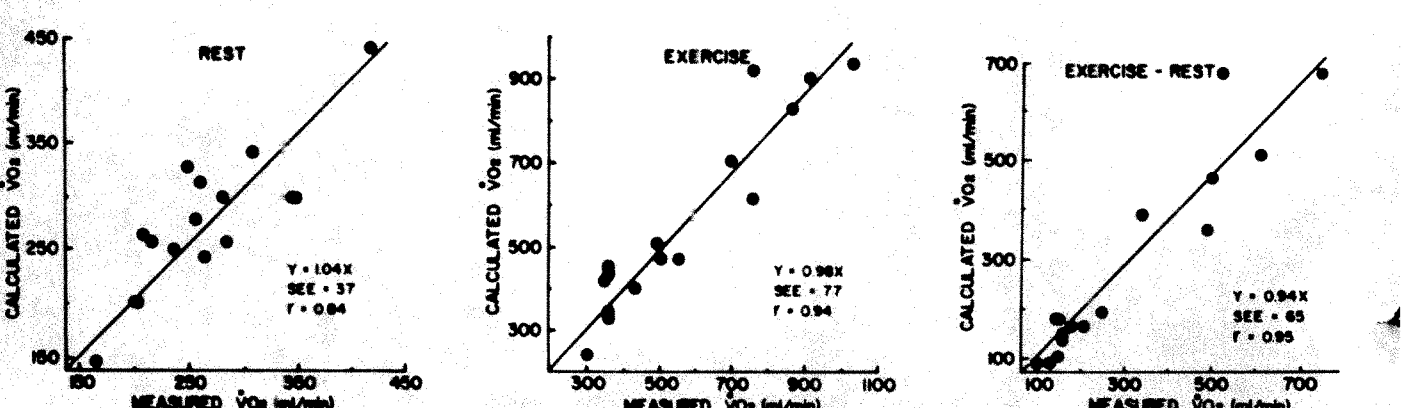

FIGURE 3. Measured compared with calculated oxygen consumption ($\dot{V}O_2$). Data were analyzed by linear regression. Symbols and panel arrangement as in Figure 1.

after drug intervention had increased cardiac output (and decreased the arteriovenous oxygen difference). We found high and very significant linear correlations between the methods at rest and during exercise and the change between rest and exercise. We compared the 2 methods of measurement of these 3 variables under 4 conditions (control treatment at rest, control treatment during exercise, vasodilator treatment at rest, and vasodilator treatment during exercise) by analysis of variance. We found no difference between the methods. We conclude that there is no large or systematic difference between these 2 methods of measurement.

Cardiac output: We measured cardiac output by thermodilution and compared it with calculated cardiac output (oxygen uptake/arteriovenous oxygen difference). We demonstrated high correlations during various conditions. In addition to biologic considerations, there are a myriad of technical considerations in the measurement of blood flow by indicator dilution technique. Special concern might be expressed about patients with chronic heart failure. Very low cardiac output might lead to a loss of cold indicator, to poor mixing, to nonmonoexponential washout of indicator, or to reappearance before washout is complete. These problems may be compounded in the use of right-heart thermodilution in the presence of tricuspid regurgitation. In fact, 6 of our patients did have clinically obvious tricuspid regurgitation secondary to right ventricular failure. Nevertheless, the linear correlations between measured and calculated variables were high and very significant. The linear regression slope was not different from 1.0, and there was no systematic offset (intercept not different from 0.0). Even higher correlations than ours have been reported[7] when thermodilution was compared with dye dilution in low cardiac output states. Despite multiple studies comparing thermodilution with other techniques for measuring cardiac output at rest, we were able to find only 1 report with scanty data at exercise; similar high correlations were reported.[8]

Oxygen uptake: We measured oxygen uptake by analysis of expired gas and compared it with calculated oxygen uptake (cardiac output × arteriovenous oxygen content difference). We demonstrated high correlations during various conditions. In comparing these 2 methods, one should take into account 2 biologic considerations. One consideration is that oxygen uptake is in the steady state. It may not be possible to obtain steady-state conditions of oxygen uptake using short work load durations near maximal oxygen uptake, as is the customary protocol for many studies including this one.[9] Nevertheless, the time constant of oxygen intake is short and, more importantly, at low levels of oxygen uptake the increments observed during non-steady state are very small.[10] Another consideration is the equality of oxygen uptake to tissue oxygen utilization, which implies no change in available oxygen stores (lung air, blood hemoglobin, or muscle myoglobin). The equality between uptake and tissue utilization is probably not correct, but the difference is believed small. These considerations could affect our 2 methods to slightly different degrees. There are also many technical considerations of oxygen uptake measurement that could affect both of our methods of measurement. Nevertheless, we found the linear correlation coefficients between measured and calculated values were high and very significant. The linear regression slope was not different from 1.0 and there was no systematic offset (intercept not different from 0.0).

Arteriovenous oxygen content: We measured the arteriovenous oxygen content difference by spectrophotometry and compared it with the calculated content difference (oxygen uptake/cardiac output). The 2 most important technical considerations of the spectrophotometric method of measuring oxygen saturation are related to a predictable relation between light absorbance and oxygen saturation, and the detection of all hemoglobin species. With measurement by spectrophotometry in *whole blood*, there is a linear relation between oxygen saturation and absorbance only down to 0.40 saturation, which limits the range of frequently used equipment (such as standard dual wave length oximeters as found in many catheterization laboratories). This limitation is not present with *hemoglobin in solution*, and modern spectrophotometers such as the one used in this study employ agents which lyse erythrocytes. Another technical consideration of oximetry is the measurement of all hemoglobin species, since oxygen saturation really represents the fraction of oxygenated hemoglobin compared with all hemoglobin species. The equipment used in this study detects all 4 common hemoglobin species. Under very rare circumstances, however, small amounts of some other hemoglobin species could be present or the hemoglobin molecule could be aberrant.

We only found modest (but significant) linear correlations between measured and calculated arteriovenous oxygen differences. However, the slope of the regression line was not different from1.0 at rest and during exercise, and there was no systematic offset (intercept of line not different from 0.0). There are 2 possible explanations for the lower correlations. First, we infer that measured arteriovenous oxygen difference has little technical variability while calculated arteriovenous oxygen difference has more variability. Similar results can be inferred from a recent report[11] which applied these comparable methods during dog studies. Calculated arteriovenous oxygen difference is the quotient of oxygen uptake divided by cardiac output, each having some variability when separate and greater variability when they appear in the same equation. In contrast, when measured arteriovenous oxygen difference is included as part of the quotient of a calculated variable (such as $\dot{V}O_2/AV\text{-}O_2$) or as part of the product of a calculated variable (such as $CO \times AV\text{-}O_2$), overall variability is reduced and the correlation coefficient is increased. This implies that for the highest accuracy, the arteriovenous oxygen difference should be measured rather than calculated. Second, however, our samples for arteriovenous oxygen difference were drawn only in the middle of a much longer sampling period of cardiac output and oxygen uptake. Therefore, if conditions were not steady state, the lower correlations we observed

might be due to a less-than-optimal sampling protocol.[12]

In summary, manipulation of Fick's equation provides the opportunity to directly measure or indirectly calculate arteriovenous oxygen difference, cardiac output, or oxygen uptake. The limitations and technical demands of each technique must be appreciated. Extremely ill patients with severe left ventricular dysfunction present an exceptional challenge to mensuration under varying conditions and during repeated measurements. For the most part, there appears to be good correlation between measured and calculated techniques.

Effects of Amyl Nitrite on Left Ventricular Relaxation In Patients With Borderline Hypertension

CHARLES Z. NAGGAR, MD, *with the technical assistance of* KENNETH STANLEY, PhD, and LORI L. DOWNING

The effects of systemic hypertension on left ventricular relaxation properties remain largely undefined. To assess such effects 22 normal volunteers and 15 patients with borderline hypertension were examined. The tangent to the echocardiographic left ventricular posterior wall endocardium was measured in diastole and was normalized for end-diastolic dimension to yield normalized velocity of relaxation. This velocity of relaxation was measured at rest and throughout inhalation of amyl nitrite. Mean value ± standard deviation (SD) from rest to peak amyl nitrite effect for the normal group and for the patients with borderline hypertension was 3.3 ± 0.6 → 7.2 ± 1.1 and 3.0 ± 0.8 → 4.4 ± 1.1 s^{-1}, respectively. All 22 persons in the normal group and 2 of the 15 patients with borderline hypertension attained normalized velocity of relaxation greater than 5.5 s^{-1} with administration of amyl nitrite. Multivariate analysis in the normal group identified heart rate, mean arterial pressure, and fractional shortening as the best predictors of normalized left ventricular relaxation velocity ($r = 0.85$; $p < 0.001$). The increase in the normalized velocity of relaxation induced by amyl nitrite is blunted in patients with borderline hypertension. These changes in left ventricular relaxation identify early cardiac involvement and may prove clinically useful in hypertensive patients.

Sustained systemic hypertension causes changes in cardiac structure and function which, when severe enough, can be recognized on routine electrocardiography and chest roentgenography,[1] but these changes occur relatively late in the course of hypertension. Echocardiography can accurately assess cardiac alterations induced by hypertension and identify the various degrees of left ventricular hypertrophy[2] and abnormal systolic performance.[1,3] Furthermore, echocardiography has demonstrated impairment in left ventricular function in hypertensive patients with minor electrocardiographic abnormalities.[4] Recently, a high incidence of echocardiographic abnormalities was detected in asymptomatic hypertensive patients in the absence of electrocardiographic or radiographic abnormalities.[5]

Because borderline hypertension predisposes to increased morbidity and mortality from cardiovascular disease,[6,7] a simple noninvasive method of identifying early cardiac involvement might have important clinical applications. Patients with borderline hypertension and early cardiac damage may require more careful follow-up and early institution of antihypertensive measures.

Echocardiographic studies describing left ventricular relaxation variables rather than systolic function in health and disease states are scarce.[8–10] This study was designed to assess the effects of borderline hypertension on one of these variables, the left ventricular velocity of relaxation.

Methods

The control group was composed of 22 normal subjects (17 women and 5 men; mean age ± SD, 26.2 ± 7.2 years) without clinical evidence of heart disease. Echocardiography was performed at rest and during inhalation of amyl nitrite, a drug chosen because of its substantial effects on heart rate, blood pressure, and left ventricular volume.[11] In 6 of these subjects, the amyl nitrite test was repeated after a 25 minute interval of rest.

Fifteen patients (5 women and 10 men; mean age 33.3 ± 10.1 years) were referred for evaluation of borderline hypertension, defined as blood pressure readings greater than 140/90 mm Hg on at least 3 outpatient visits but normal pressure recorded

at other times.[6,7] All were asymptomatic and showed no evidence of target organ damage. All patients had regular sinus rhythm with electrocardiographic findings that were considered normal, and they did not fulfill any criteria for left ventricular hypertrophy or left atrial conduction abnormalities. At the time of the study no patient was receiving any therapy. All patients and normal subjects gave informed consent.

Echocardiograms were recorded using a Unirad model C echocardiograph and a 2.25 MHz transducer. High quality echograms of the left ventricular cavity, just below the posterior leaflet of the mitral valve, were recorded on a Honeywell Visicorder, model 1856, along with simultaneous electrocardiograms. Blood pressures were taken by standard sphygmomanometric methods and were expressed as mean arterial pressure estimated as the sum of the diastolic pressure plus one third of the pulse pressure. External carotid pulse tracings, phonocardiograms, and blood pressure were recorded simultaneously with the echocardiogram at rest and at intervals of 15, 30, 45, 60, and 120 seconds from beginning of inhalation of amyl nitrite. The left ventricular ejection time was measured from the external carotid pulse recording.

Recordings of the posterior wall endocardium were analyzed as described by Fogelman et al.[9] and Wise.[10] The velocity of left ventricular relaxation was determined by drawing a tangent to the steepest point of the diastolic limb of the posterior wall endocardium. At least 3 beats from each recording were analyzed, and the average value was reported. The ventricular end-diastolic dimension was measured at the height of the electrocardiographic R wave,[12] and the left ventricular end-systolic dimension was measured at the summit of the posterior wall endocardium.[12] The concept of normalized velocity, as described by Mirsky et al.,[13] has previously been employed in the echocardiographic evaluation of left ventricular function.[14] The same concept is used in the present study to evaluate left ventricular relaxation to permit meaningful comparison among patients.

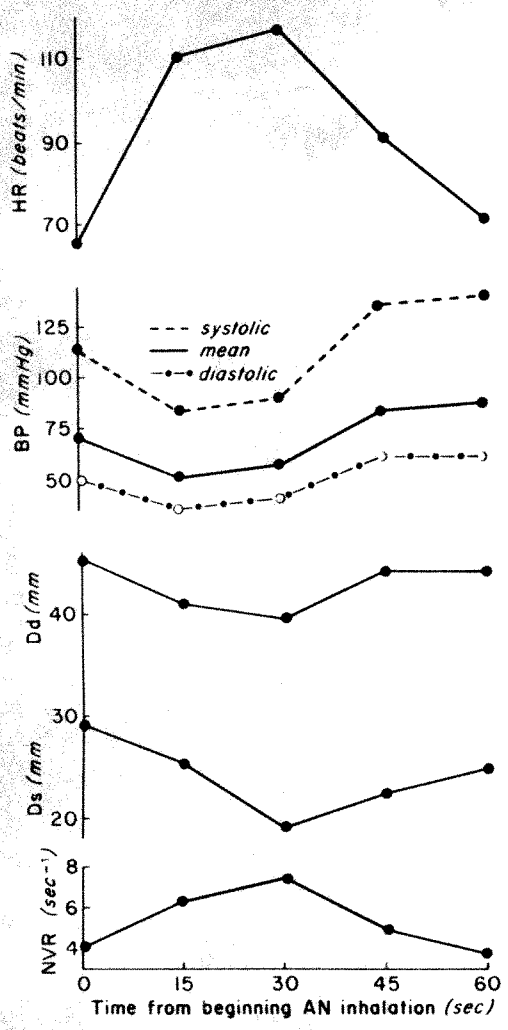

FIGURE 1. Typical effects of amyl nitrite inhalation in a normal subject. AN = amyl nitrite; BP = blood pressure; Dd = left ventricular end-diastolic dimension; Ds = left ventricular end-systolic dimension; HR = heart rate; NVR = normalized left ventricular relaxation velocity; sec = seconds.

Normalized velocity of left ventricular relaxation (NVR) was calculated according to the formula NVR (s^{-1}) = VR/Dd, where VR = left ventricular relaxation velocity in centimeters per second and Dd = left ventricular end-diastolic dimension in centimeters. The mean rate of circumferential fiber shortening ($V\bar{c}f$) was calculated according to the formula ($V\bar{c}f$ (circ/s) = (Dd − Ds)/(Dd × LVET), where circ = circumference, Dd = left ventricular end-diastolic dimension in centimeters, Ds = left ventricular end-systolic dimension in centimeters, and LVET = left ventricular ejection time. The fractional shortening (FS) of the left ventricular internal dimension was calculated according to the formula FS = (Dd − Ds)/Dd, where Dd = left ventricular end-diastolic dimension in centimeters and Ds = left ventricular end-systolic dimension in centimeters.

Quantitative assessment of the hemodynamic effect of amyl nitrite was estimated from the change in the product of the mean arterial pressure multiplied by the cycle length and the product expressed in mm Hg × seconds. Normalized velocity of relaxation was assigned as a dependent variable whereas age, heart rate, mean arterial pressure, fractional shortening, left ventricular end-diastolic dimension, and left ventricular end-systolic dimension were considered predictor variables. Data were analyzed using a multivariate statistical analysis. The multivariate linear model routine of the Statistical Package for Social Sciences[15,16] is used to test the hypothesis of no correlation between normalized velocity of relaxation and the predictor variables. The hypothesis of equality of group means was evaluated using the unpaired or paired t test as appropriate between the normal and the borderline hypertensive groups.[15]

Results

At the time of the study the mean ± SD resting systolic and diastolic pressures were 109.3 ± 10.7 and 71.9 ± 9.7 mm Hg for the normotensive subjects and 140.5 ± 14.8 and 90.3 ± 12.0 mm Hg for the borderline hypertensive patients, respectively. No significant difference was noted in the following echocardiographic variables between the normotensive and borderline hypertensive groups: left ventricular end-diastolic and end-systolic dimensions, interventricular septal thickness, posterior wall thickness, and left atrial size. The normal responses of heart rate, blood pressure, left ventricular end-diastolic and end-systolic dimensions, and normalized left ventricular relaxation velocity to amyl nitrite are shown in Figure 1. In the 6 normal subjects undergoing 2 separate amyl nitrite challenges 25 minutes apart, mean resting normalized left ventricular velocity of relaxation during the 2 control periods were identical at 3.3 ± 0.5 s^{-1}. The consistency and reproducibility of the hemodynamic effects of amyl nitrite are shown in Table I, which compares the changes in the variables measured before and at peak effect of amyl nitrite during 2 separate challenges in these first 6 normal subjects. The results showed that amyl nitrite produced nearly the same hemodynamic changes in the same person.

The values for the normalized left ventricular velocity of relaxation for the 22 normal subjects at rest and at peak effect of amyl nitrite were 3.3 ± 0.6 and 7.2 ± 1.1 s^{-1}, respectively ($p < 0.001$). Heart rate, fractional shortening, and circumferential fiber shortening increased significantly while left ventricular end-diastolic and end-systolic dimensions as well as mean arterial pressure decreased at peak effect of amyl nitrite (Table II). In every instance, amyl nitrite induced a marked increase in the normalized left ventricular relaxation velocity. In no instance did this value fail to reach 5.5 s^{-1} or more at peak amyl nitrite effect.

In the 22 normal subjects we were able to collect echocardiographic and electrocardiographic data and blood pressure and external carotid recordings at different intervals from the beginning of inhalation of amyl nitrite until the peak effect of the drug was reached. These recordings yielded 77 data points in the 22 subjects. Heart rate, mean arterial pressure, left ventricular end-systolic dimension, and fractional shortening showed decreasing influence on the normalized left ventricular relaxation velocity ($r = 0.80, -0.66, -0.59$, and 0.56, respectively). Multivariate linear regressions between normalized left ventricular relaxation

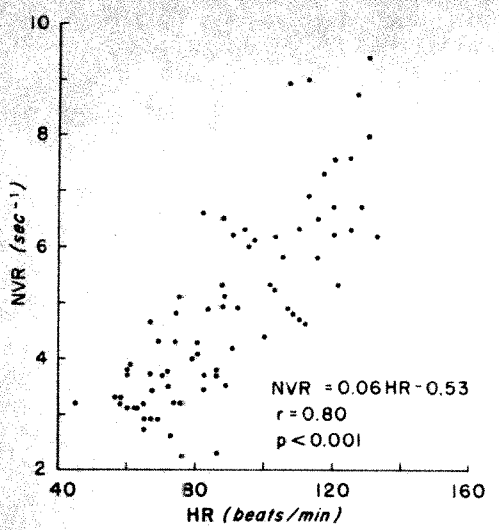

FIGURE 2. Relation between heart rate (HR) and normalized left ventricular relaxation velocity (NVR) during amyl nitrite inhalation in 22 normal subjects. Data points were collected at 15 second intervals from the beginning inhalation of amyl nitrite until the peak effect of the drug was reached.

velocity and predictor variable heart rate, mean arterial pressure, fractional shortening, and left ventricular end-systolic dimension showed a significant correlation coefficient ($r = 0.85$; $p < 0.001$): NVR = 2.72 + 0.05 HR − 0.03 MAP + 1.70 FS −0.02 Ds, where NVR = normalized left ventricular relaxation velocity, HR = heart rate, MAP = mean arterial pressure, and FS = fractional shortening.

The partial regression coefficients for heart rate and mean arterial pressure were statistically significant ($p < 0.001$). Neither fractional shortening nor left ventricular end-systolic dimension contributed significantly to the overall correlation. However, when mean arterial pressure is excluded from the correlation, fractional shortening assumed a significant influence on the normalized left ventricular relaxation velocity. Figure 2 depicts the relation between normalized left ventricular relaxation velocity and heart rate. The interplay between normalized left ventricular relaxation velocity, heart rate, mean arterial pressure, and fractional shortening of the 77 data points from the normal subjects is illustrated by a 3-dimensional graph (Fig. 3).

For the borderline hypertensive patients, the mean resting normalized left ventricular relaxation velocity did not differ significantly from the values in the normotensive group (3.0 ± 0.8 versus 3.3 ± 0.6 s^{-1}, respectively; $p > 0.20$). However, at peak amyl nitrite effect, even though normalized left ventricular relaxation velocity showed similar directional changes in both groups, the control group achieved a significantly higher peak than the patients with borderline hypertension (7.2 ± 1.1 versus 4.4 ± 1.1 s^{-1}; $p < 0.001$), as shown in Figure 4. The increment change of mean arterial pressure-cycle length product showed a comparable decrease in both groups (45.2 ± 11.0 versus 48.3 ± 18.8 mm Hg × s for the normal and the borderline hypertensive groups, respectively; $p = 0.53$).

Within the linear model for normalized left ventricular relaxation velocity, age as the only predictive variable showed a poor correlation ($r = 0.007$). Furthermore, when other predictor variables (heart rate, mean arterial pressure, and fractional shortening) were included, the contribution of age to the overall correlation was insignificant ($F < 1.0$; $p > 0.5$).

For the 2 groups studied, the presence of borderline pressure elevation was compared as an additional variable in the linear model for normalized left ventricular relaxation velocity. This allowed us to evaluate the effect of borderline hypertension on the relaxation velocity after correcting for other predictive variables such as age, heart rate, mean arterial pressure, and fractional shortening. The presence of borderline hypertension correlated with a blunted increase in the normalized left ventricular relaxation velocity in response to amyl nitrite ($p < 0.001$; $F_{1,70} = 31.6$).

Discussion

This study demonstrates that the posterior wall of the left ventricle moves rapidly during diastolic relaxation in normal subjects and those with borderline hypertension. Our values for the normal resting posterior wall endocardial velocity of relaxation are comparable with those previously reported.[9,10] Mean values for the normalized left ventricular posterior wall relaxation velocity did not differ significantly from beat to beat, nor did they change in time when we compared resting values for the 6 normal subjects during 2 control periods. The 2 separate challenges of amyl nitrite in each of the 6 normal subjects showed that amyl nitrite consistently induced nearly the same hemodynamic changes in the same person. The reproducibility of this measured variable of relaxation velocity was established both at rest and after inhalation of amyl nitrite.

Variables predictive of normalized left ventricular relaxation velocity in normal subjects: Relaxation is an active process, requiring approximately 15% of the total myocardial energy probably for pumping calcium back into the sarcoplasmic reticulum.[17,18] Various mechanical and chemical stimuli have been shown to alter left ventricular relaxation.[19–21] Amyl nitrite was chosen as a simple, safe noninvasive challenge to induce changes in factors known to affect the relaxation of the intact left ventricle, such as heart rate, inotropic state, and end-systolic volume.[20,21] All 3 factors were altered by amyl nitrite in each of the subjects studied. In the present study, amyl nitrite consistently increased diastolic velocity of relaxation in every subject. In the normotensive subjects, heart rate, mean arterial pressure, left ventricular end-systolic dimension, and fractional shortening showed decreasing relative influence on normalized left ventricular relaxation velocity. However, the profound effect of heart rate may well be a combination of a direct influence and an indirect one through inotropic stimulation.[21] Although the changes induced by amyl nitrite are those expected from de-

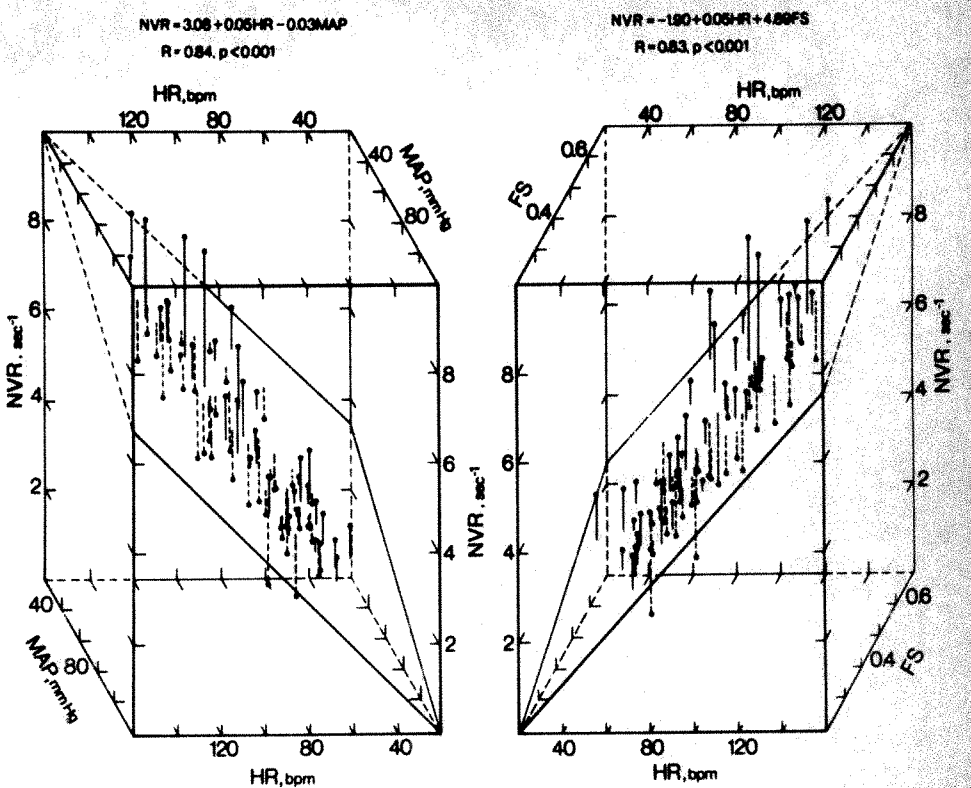

FIGURE 3. Relation between the normalized left ventricular relaxation velocity and its best predictor variables in normal subjects. The cube on the **left-hand side** is a 3-dimensional graph depicting the normalized left ventricular relaxation velocity on the y axis versus mean arterial pressure on the z axis, and heart rate on the x axis. The cube on the **right-hand side** depicts the relation between normalized left ventricular relaxation velocity on the y axis versus heart rate on the x axis and fractional shortening of the z axis. The 2-dimensional plane within each cube is a best fit plane predicted by the equations derived from the multivariate linear model. Data points falling above the planes are connected to them by **solid lines;** points falling below the planes are connected to the planes by **broken lines.** The normalized left ventricular relaxation velocity (NVR) is linearly related to the heart rate (HR) and fractional shortening (FS) and inversely related to mean arterial pressure (MAP).

creased afterload or increased stroke volume,[22] the increase in cardiac output has been shown to be related primarily to the increase in heart rate.[23]

Effects of amyl nitrite on normotensive versus borderline hypertensive subjects: The resting normalized left ventricular relaxation velocity did not discriminate between normal subjects and borderline hypertensive patients, but a striking difference in normalized left ventricular relaxation velocity was seen at peak amyl nitrite effect. None of the 22 normal subjects showed a velocity of less than 5.5 s^{-1}, whereas 13 of 15 patients with borderline hypertension had a velocity of less than 5.5 s^{-1} at peak effect of amyl nitrite. It seems unlikely that this difference between the 2 groups was due to variation in hemodynamic alterations, because amyl nitrite induced comparable hemodynamic changes in both groups. (The mean arterial pressure-cycle length product decreased by comparable increments in both groups.)

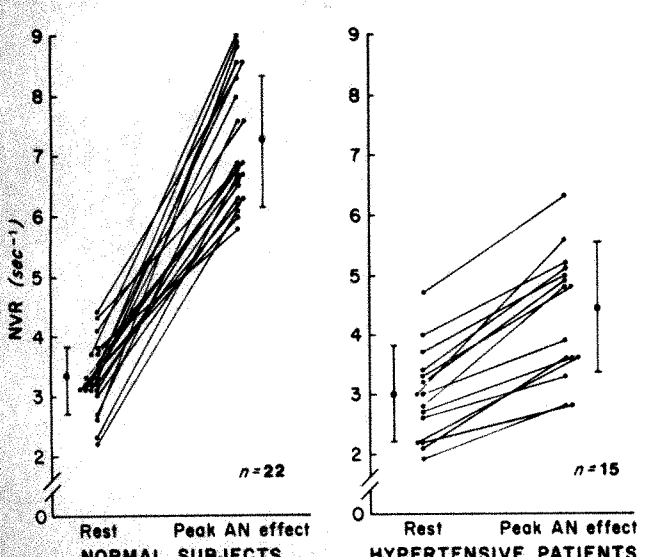

FIGURE 4. Peak effect of amyl nitrite (AN) inhalation on the normalized left ventricular relaxation velocity (NVR) in the 2 groups studied. **Bars** on both sides of the graphs depict means ± standard deviation.

The blunted response of the normalized left ventricular relaxation velocity to amyl nitrite in the borderline hypertensive group might be due to failure of normal relaxation unmasked by the more rapid left ventricular diastolic filling induced by amyl nitrite. A similar mechanism was proposed[24] to explain the increased intensity of recorded third and fourth heart sounds noted in patients with coronary heart disease given amyl nitrite. Harrison et al.[25] found a definite slowing of total isovolumic relaxation time with advancing age independent of resting heart rate. However, in the present study, age correlated poorly with the magnitude of change in the normalized left ventricular relaxation velocity induced by amyl nitrite ($r = 0.11$; $p > 0.05$). Recognizing the difference in mean ages between the two groups we looked at age as the *only* predictive variable within the linear model for normalized left ventricular relaxation velocity. Age as the only

predictor variable showed a poor correlation (r = 0.007) and could not explain the difference in response to amyl nitrite.

Implications of the study: Because hypertension affects the left ventricular myocardium uniformly, the normalized left ventricular posterior wall relaxation velocity may show the earliest measurable change of myocardial dysfunction occurring before alterations in mass or contractility are evident. Studies are currently underway to evaluate the effect of pharmacologic therapy in the treatment of borderline hypertension and its effect on this normalized left ventricular relaxation velocity. The echocardiographic amyl nitrite stress test may prove to be a simple, noninvasive tool for the detection and study of the early involvement of cardiac muscle in hypertension.

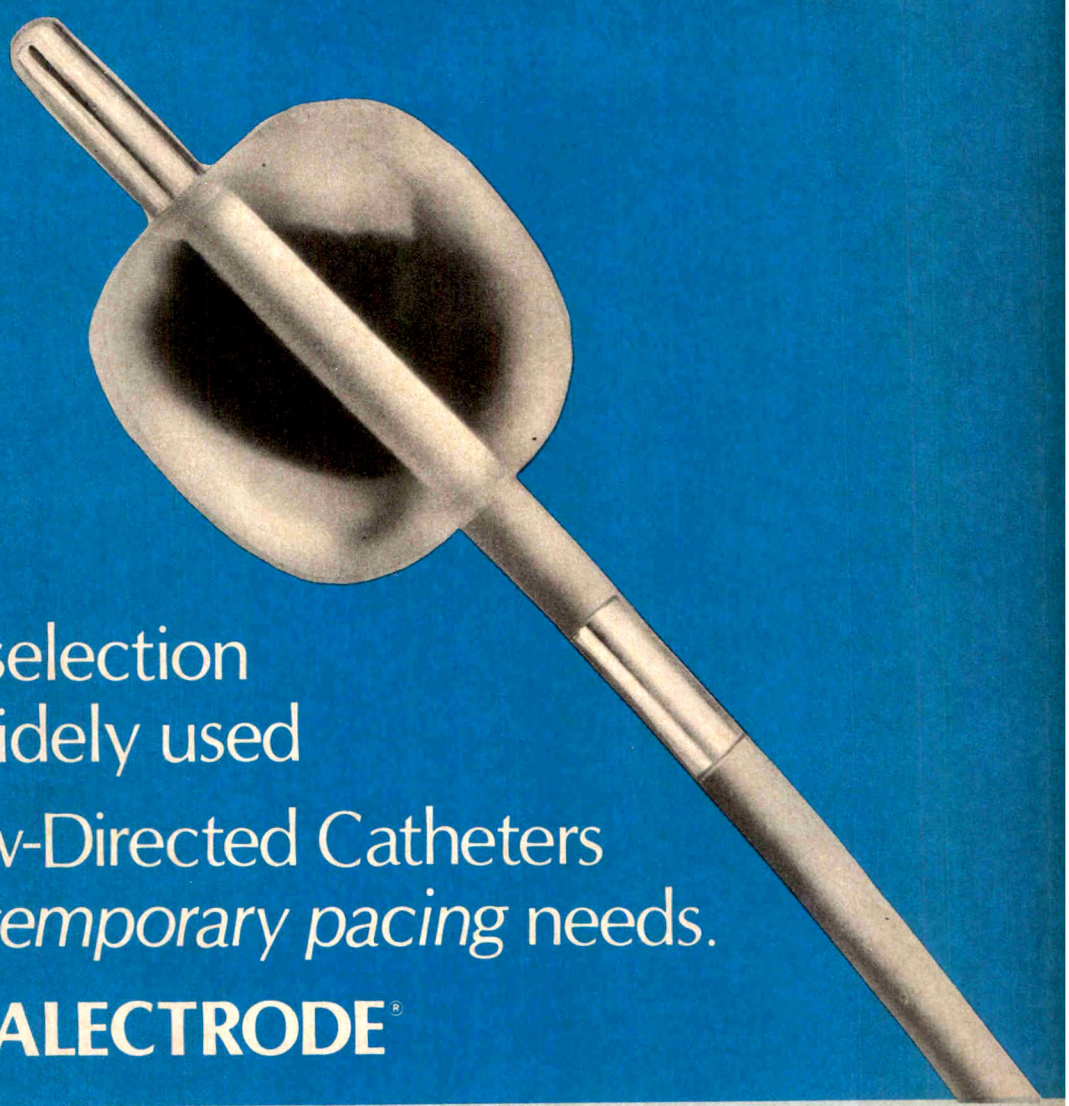
THE LEADER
in Balloon Flow-Directed Pacing

ELECATH®



The widest selection and most widely used Balloon Flow-Directed Catheters for all your *temporary pacing* needs.

ELECATH® BALECTRODE®

- The *only* major manufacturer of Balloon Flow-Directed pacing kits to offer non-corroding *platinum* electrodes to assure optimal physiological response, and to prevent the migration effect seen in stainless steel electrodes.
- Balloon Flow-Directed assures easy, accurate placement for rapid and complete capture.
- Two French sizes are available: 3 French (KBE 1) and 5 French (KBE 2) for various patient physiological requirements.
- Complete, convenient, sterile kit, consisting of an introducer, shielded EKG adapter, and vented syringe for exact, accurate balloon inflation.

You can rely on your ELECATH representative to provide specialized service and recommendations on the complete ELECATH Family of pacing products.

PROCARDIA®
(NIFEDIPINE) Capsules 10 mg
PROCARDIA is the beginning of a new age in the treatment of angina:
The Calcium Age.
It is now known that calcium ions, working at the cellular level, regulate the degree of vasoconstriction and, thereby, play a critical role in the anginal attack.
PROCARDIA acts at the cell membrane to selectively block calcium access to the contractile process in the arterial cell.
Through this action, PROCARDIA manages:
—vasospastic angina, by preventing coronary artery spasm and increasing myocardial O_2

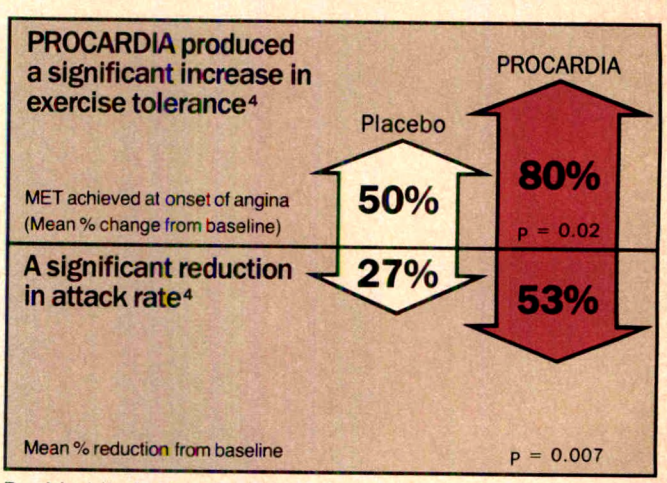
PROCARDIA
(NIFEDIPINE) *Capsules 10 mg*

PROVEN EFFECTIVE ACROSS THE SPECTRUM OF ANGINA

Contemporary medical opinion holds that the pathophysiology of angina is a spectrum ranging from pure, fixed atherosclerotic lesion to pure coronary artery spasm. Many patients, however, are believed to have a combination of both lesion and spasm.[2,3]

Angina due to pure fixed lesion can be prevented by reducing oxygen demand. Angina due to coronary artery spasm can be treated by preventing the spasm itself, thereby increasing oxygen supply. With this new understanding of angina, optimal antianginal therapy should provide this dual action: increasing O_2 supply while reducing O_2 demand.

In effort angina*
(when symptomatic despite conventional therapy)

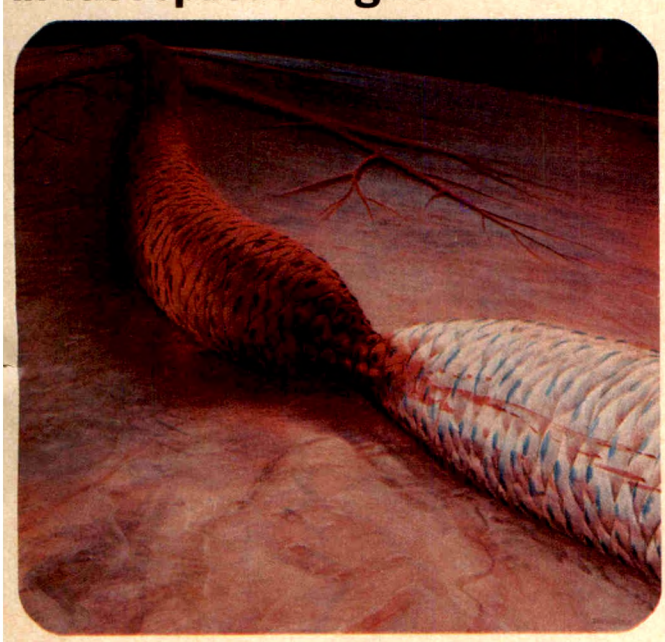


Double-blind, placebo-controlled, crossover 20-week study of 32 patients (27 evaluated for attack rate; 19 for exercise tolerance). Mean PROCARDIA dosage: 51 mg/day.

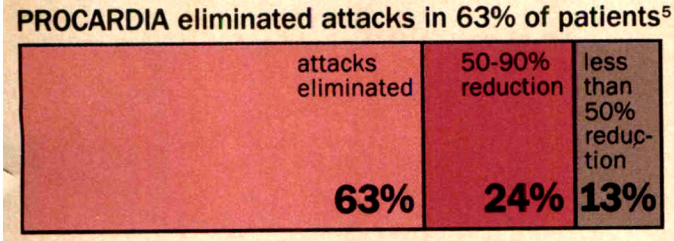
*In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Please see PROCARDIA Brief Summary on last page.

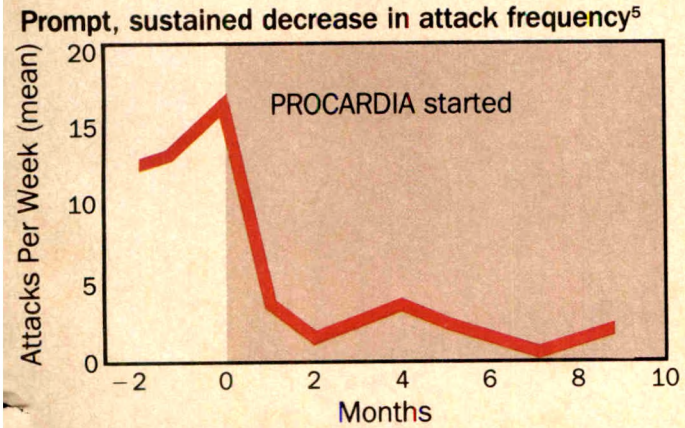
In vasospastic angina



PROCARDIA eliminated attacks in 63% of patients[5]

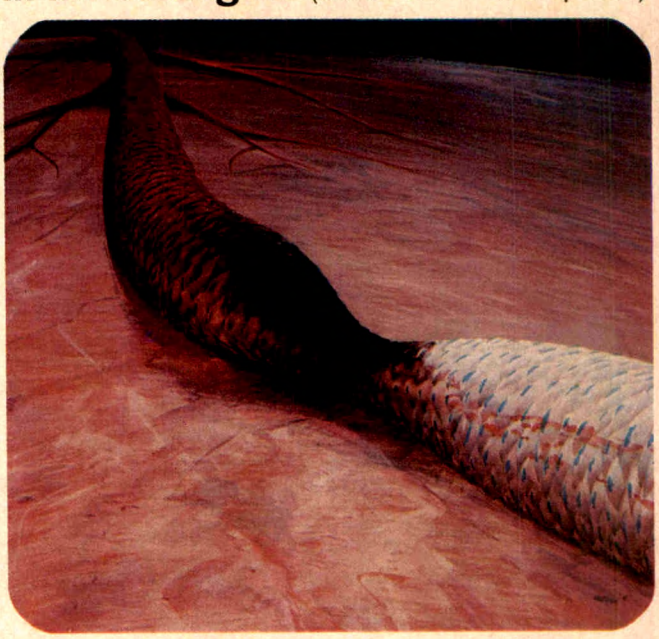


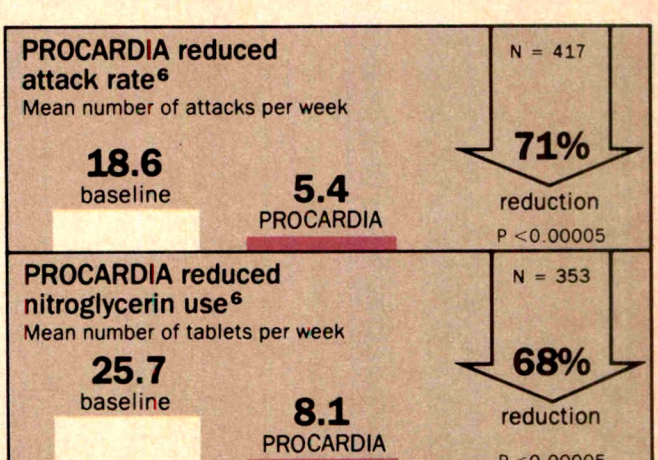
Prompt, sustained decrease in attack frequency[5]



Long-term, open study of 127 patients unresponsive to beta blockers and/or nitrates with symptoms of myocardial ischemia and demonstrated coronary artery spasm. PROCARDIA dosage: 40 to 160 mg/day.

In mixed angina (fixed lesion and spasm)





Studies of patients with mixed angina characterized by pain at rest and effort. Most patients (89%) were initiated on nitrate and/or beta blocker therapy but remained symptomatic. Minimum duration of nifedipine treatment two months. Nifedipine dosage: 30 to 120 mg/day.

PROCARDIA®
THE FIRST ORAL CALCIUM CHANNEL BLOCKER

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

ANGINA MANAGEMENT BEYOND BETA BLOCKERS

—Beta blockers prevent angina primarily by lowering myocardial oxygen demand. Like these agents, PROCARDIA reduces myocardial oxygen demand. However, PROCARDIA provides an added dimension of angina control by increasing myocardial oxygen supply where coronary artery spasm is present.

—Beta blockers can actually cause spasm. PROCARDIA prevents spasm.

—Beta blockers decrease myocardial perfusion in poststenotic areas. PROCARDIA increases myocardial perfusion to both normal and poststenotic areas.

—Beta-blocker treatment is limited in patients with myocardial dysfunction, COPD, asthma, bundle branch blocks, and diabetes. PROCARDIA can be given safely in all these groups of patients.

—The hypotensive effect of PROCARDIA is usually modest and well tolerated, however, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or subsequent upward dosage adjustment, and may be more likely with concomitant beta blockers.

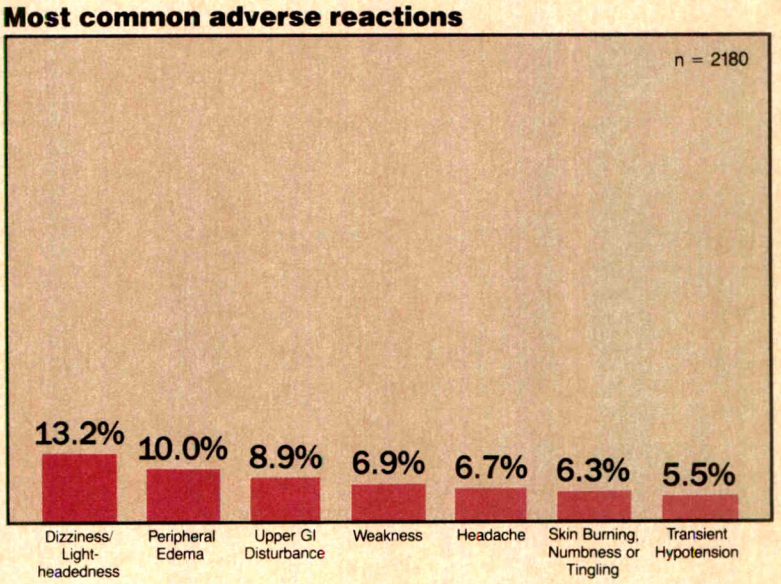
—Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA, or at the time of dosage increases. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers, if possible, rather than stopping them abruptly before beginning PROCARDIA.

—Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

THE FIRST ORAL CALCIUM CHANNEL BLOCKER...

PROVIDES PROTECTION WITH A MILD SIDE-EFFECT PROFILE

Most common adverse reactions



Information is drawn from a large uncontrolled experience in 2180 patients and presents the most frequent side effects reported with PROCARDIA.

AN ADDED ADVANTAGE: COMPATIBILITY

—MAY BE USED WITH A WIDE VARIETY OF OTHER AGENTS

—CAN BE USED WITH NITRATES AND BETA BLOCKERS WITH CAUTION (See Warnings and Precautions)

THE FIRST ORAL CALCIUM CHANNEL BLOCKER FOR THE MANAGEMENT OF ANGINA

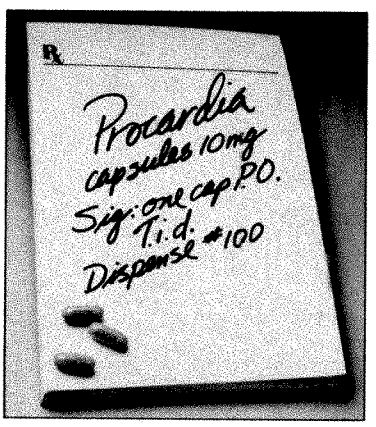
PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Proven effective when used alone.

Enhanced effectiveness when combined with beta blockers.

Convenient dosing

Start with:	1	10-mg capsule *t.i.d.*
Titrate to:	2	10-mg capsules *t.i.d.*
Titrate to:	3	10-mg capsules *t.i.d.*



For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely. Maximum dose 180 mg/day.

PROCARDIA® CAPSULES For Oral Use
(nifedipine)

BRIEF SUMMARY

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Increased Angina/Beta Blocker Withdrawal: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Pregnancy: Category C.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA Capsule contains 10 mg of nifedipine. PROCARDIA Capsules are supplied in amber glass bottles of 100 capsules (NDC 0069-2600-66).

The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Significance of Abnormal Electrocardiograms In Highly Trained Athletes

DAVID G. OAKLEY, MA, and CELIA M. OAKLEY, MD, FRCP

Electrocardiographic and other abnormalities of highly trained athletes are well recorded but not well enough known, and the more extreme changes still cause diagnostic confusion. This problem was exemplified by 10 athletes, all referred to us by cardiologists because of a diagnosis of organic heart disease. After thorough investigation, including catheter studies, all but 1 of these patients was regarded as normal and all returned to competitive sports. The criteria for diagnosing heart disease in athletes are discussed in light of the findings in 10 patients. Exercise electrocardiography and echocardiography help to exclude organic disease, but left heart catheterization is justified when doubt still exists.

For many years cardiologists have been aware that highly trained athletes may show some cardiovascular features that would be considered abnormal in an untrained person. This "athlete's heart syndrome" may include sinus or junctional bradycardia at rest, third and fourth heart sounds, systolic murmurs, a large heart on the chest radiograph, and a variety of electrocardiographic abnormalities. Despite descriptions of this cardiovascular syndrome, many athletes are still being misdiagnosed. The false trail is usually initiated by electrocardiographic findings, and with the more frequent use of the electrocardiogram in routine examinations this trend is likely to increase. The opposite aspect is equally important because people with significant heart disease may be capable of considerable sports achievement during which they may be at risk.[1,2]

Separation of normality from disease in athletes is likely to become an increasingly common problem. Over the past 4 years 10 athletes were referred to the Hammersmith and Sheffield Hospitals for assessment. All these patients had previously been seen by consultant cardiologists who had already advised them to stop training and relinquish their sporting ambitions, but had referred them for a further opinion. Because of the disruption in their lives caused by the diagnosis of heart disease, it was thought essential to perform angiographic as well as noninvasive investigations. This report contains the clinical noninvasive and catheterization data on these patients. The range of "abnormalities" is illustrated and the criteria for diagnosing organic heart disease are discussed.

From the Cardiothoracic Unit, Northern General Hospital, Sheffield, and The Division of Cardiovascular Disease, Royal Postgraduate Medical School, Hammersmith Hospital, London, England. Manuscript received November 23, 1981; revised manuscript received March 24, 1982, accepted April 7, 1982.

Address for reprints: David G. Oakley, MA, Cardiothoracic Unit, Northern General Hospital, Herries Road, Sheffield, S5 7AU, England.

Methods

Patients: All 10 patients were athletes actively engaged in vigorous training and competition. In each patient electrocardiography had been performed, either as part of a routine examination or after some trivial complaint. In each case a cardiologist had diagnosed cardiac disease and the patient had been referred for a second opinion. All patients had been advised to stop training, 2 had received an unfavorable life insurance rating, and 1 had been refused renewal of his private pilot's license. Table I lists some relevant information about each athlete. Patient 1 is West Indian; the rest are Caucasian.

Investigations: The following investigations were performed in all patients: history, physical examination, chest radiography, resting electrocardiography, M-mode echocardiography, treadmill exercise electrocardiography using the Frank orthogonal lead system and modified Bruce protocol, and left heart catheterization with left ventricular angiography in the 45° right anterior oblique projection. In all but 2, selective coronary arteriography was performed in multiple views using the Judkins technique. Three patients underwent right heart catheterization, and in 1 patient right ventricular biopsy had been performed elsewhere.

TABLE I Referral Data on Athletes

Athlete	Weight (kg)	Age (yr)	Height (cm)	Sport	Referring Diagnosis	Reason for Initial Examination	Result of First Consultation
1	82.1	18	190	Basketball (national team)	Cardiomyopathy	Routine examination	Stopped training; stopped career in physical education
2	68.5	37	180	Competitive cycling	Uncertain	Routine examination	Stopped cycling
3	77.4	24	187	Squash	HOCM	One episode of dizziness	Stopped training
4	85.8	31	184	Judo (Olympic)	HOCM	Routine examination	Missed Olympic games
5	79.4	26	185	Football	Uncertain	Palpitation	Stopped training
6	72.5	41	177	Middle distance athlete (Olympic)	Ischemic heart disease	Life insurance	Stopped training; insurance rating
7	74.2	24	180	Tennis (professional)	Ischemic heart disease	Palpitation	Dropped from professional circuit
8	70.0	23	176	Competitive cycling	Cardiomyopathy	Life insurance	Insurance loading
9	67.8	19	175	Long distance athlete	Cardiomyopathy	Mild palpitation	Stopped running
10	71.0	26	181	Middle distance athlete	Ischemic heart disease	Routine examination	Private pilot's license refused

HOCM = hypertrophic obstructive cardiomyopathy.

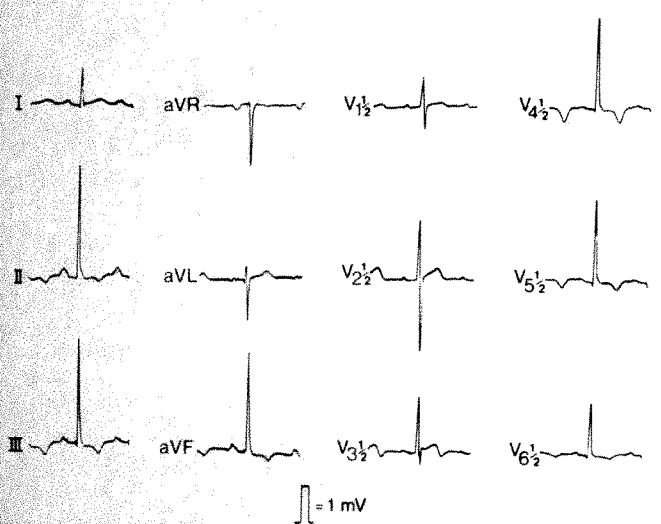

FIGURE 1. Patient 1. Electrocardiogram of international basketball player showing left ventricular hypertrophy and T-wave changes. Paper speed 25 mm/s. (Note half standardization in chest leads.)

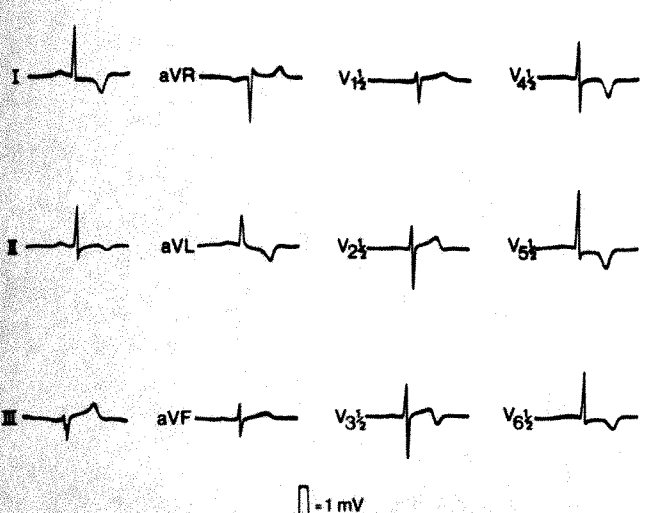

FIGURE 2. Patient 4. Electrocardiogram of Olympic judo competitor showing left ventricular hypertrophy with "strain" pattern. (Note half standardization in chest leads.)

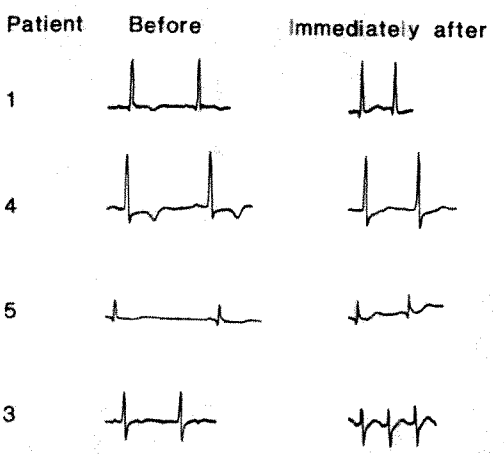

FIGURE 3. Exercise tests of Patients 1, 3, 4, and 5. Lead X (Frank orthogonal lead system) before and immediately after exercise. Paper speed 25 mm/s. Note "normalization" of preexercise T-wave inversion.

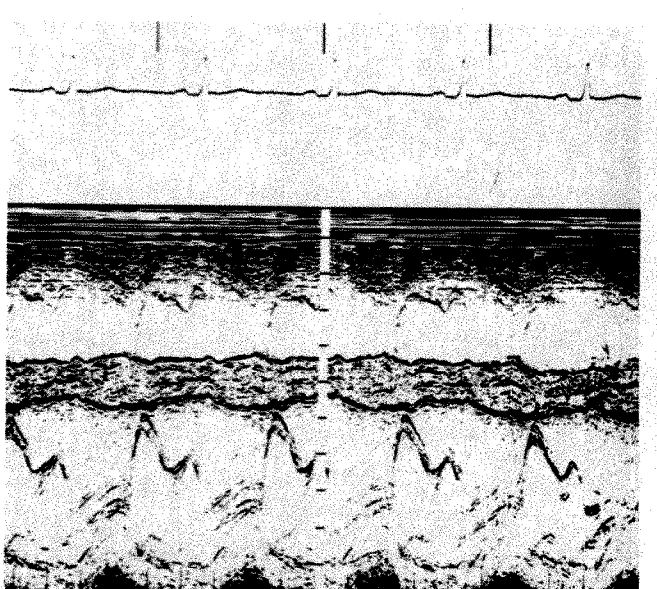

FIGURE 4. Echocardiogram of Patient 6. Note the thick septum (1.4 cm) and vigorous left ventricular posterior wall motion (0.9 cm thick). Mitral valve movement is normal. Left ventricle cavity dimensions: systolic 2.9 cm, diastolic 4.6 cm.

TABLE II Noninvasive Data

Athlete	Examination	Chest Radiography	ECG	Exercise ECG	Echocardiography
1	Systolic murmur, S_3	CTR 1:2	Gross LVH	T-wave normalization	Concentric hypertrophy
2	Palpable LV, S_4	Normal	LVH, incomplete RBBB	No change	Concentric hypertrophy
3	S_3	Normal	LVH, RAD	T-wave normalization	Septum:LVPW = 1.6:1
4	Systolic murmur, S_4	CTR 1:2	LVH	T-wave normalization	Septum:LVPW = 1.9:1
5	Normal	Normal	LVH	T-wave normalization	Normal
6	S_4	Normal	T-wave changes	No change	Normal
7	S_4, LV+	Normal	Anterior infarct	No change	Normal
8	Systolic murmur, S_4	Normal	LVH, Q-T prolongation	No change	Concentric hypertrophy
9	Normal	Normal	LVH	T-wave normalization	Normal
10	S_3, LV+	Normal	T-wave changes, LAD	No change	Normal

CTR = cardiothoracic ratio; ECG = electrocardiography; LAD = left axis deviation; LV = left ventricle; LV+ = palpable left ventricular impulse; LVH = left ventricular hypertrophy; LVPW = left ventricular posterior wall; RAD = right axis deviation; RBBB = right bundle branch block.

Results

Noninvasive Data (Table II)

Physical examination: No patient was hypertensive. A third heart sound was heard in 3 patients and a fourth sound in 5. In 3 of the 5 patients with a fourth sound an atrial impulse was palpable at the apex. A soft ejection systolic murmur was present in 3.

Chest radiography: In 2 patients the cardiothoracic ratio was at the upper limit of normal (1:2) with a left ventricular contour. All other radiographs were normal.

Electrocardiography (Fig. 1 and 2): Seven patients had left ventricular hypertrophy using standard criteria[3] and T-wave changes. Two had T wave changes only. Only 1 patient (Patient 7) had anterior Q waves suggesting previous infarction.

Exercise electrocardiography (Fig. 3): In 5 patients T-wave abnormalities became "normal" on exercise. All patients achieved heart rates in excess of 150 beats/min and their exercise capacity was outstanding. No arrhythmias were noted.

Echocardiography: Five echocardiograms were within normal limits. Three demonstrated symmetrical thickening of both septum and posterior left ventricular wall with left ventricular cavity dimensions at the upper limit of normal. One patient (Patient 3) had a septum to left ventricular posterior wall thickness ratio of 1.6:1 with no other evidence of hypertrophic cardiomyopathy (Fig. 4). Echocardiograms of 3 first degree relatives of this patient were completely normal. Patient 4 had a septum to left ventricular posterior wall thickness ratio of 1.9:1 with some systolic anterior motion of the mitral valve, but this paralleled the posterior wall and did not hit the septum. The aortic valve did not show mid-systolic closure. It was not possible to examine any of his relatives.

Cardiac Catheterization Data (Table III)

Left heart: In 5 patients the ventricular angiograms were normal, with no dyskinesia and a normal ejection fraction. In 2 the left ventricle was regarded as slightly enlarged with concentric hypertrophy of the walls, but the ejection fraction was normal. Patient 7 demonstrated definite anterior dyskinesia with good function of the remaining segments of the ventricle. In 2 patients the angiograms suggested left ventricular hypertrophy because of the vigor of contraction and prominence of the papillary muscles. In no case was the cavity bent or misshapen. In these 2 patients catheter tip transducers were inserted into the left ventricle. No outflow gradient could be measured either at rest or on provocation with amyl nitrite, isoprenaline, or extrasystoles.

Coronary arteriography disclosed that all coronary arteries were widely patent in the 8 patients examined, including Patient 7 who showed anterior Q waves and anterior wall dyskinesia. Right ventricular pressure and angiography were normal in 3 patients. Biopsy of the right ventricle had been performed elsewhere in 1 patient thought to have a congestive cardiomyopathy. This was reviewed and showed some hypertrophy of the muscle fibers with a possible slight increase in interstitial fibrosis. Neither finding was thought to be incompatible with a healthy athlete.

Discussion

On the basis of these investigations all but 1 of these 10 athletes were regarded as having a normal heart. The remaining patient (Case 7) was thought to have had a previous infarct, possibly from trauma while playing rugby football. All patients have returned to their training and competition and remain free of symptoms

TABLE III Catheterization Data

Patient	Left Ventricular Angiography	Coronary Arteriography	Right Heart Catheterization and Angiography
1	Concentric hypertrophy and dilatation	Normal	Normal (including biopsy)
2	Normal	—	—
3	Hypertrophy, no gradient	Normal	—
4	Hypertrophy, no gradient	Normal	—
5	Normal	Normal	Normal
6	Normal	Normal	—
7	Anterior dyskinesia	Normal	—
8	Hypertrophy, no gradient	—	Normal
9	Normal	Normal	—
10	Normal	Normal	—

— = not done.

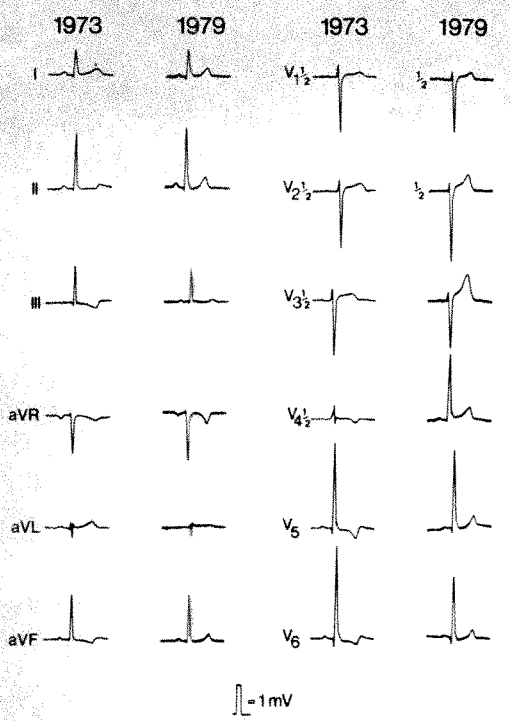

FIGURE 5. Electrocardiogram of an Olympic walker (not included in Table I) before and 6 years after cessation of training. Note drop in voltage in V_5 and V_6 and resolution of inferolateral T-wave inversions. (Note half standardization in leads V_1–V_4 in 1973 record.)

during a follow-up period of 6 months to 5 years. Two patients have had an abnormal insurance rating withdrawn and 1 has regained his private pilot's license.

Diagnostic significance of abnormal cardiovascular and electrocardiographic findings: The cardiovascular and electrocardiographic abnormalities observed in these patients are similar to those described by other investigators.[4,5] Therefore, it is not our purpose to illustrate a well-known electrocardiographic phenomenon, but rather to discuss the diagnostic significance of these changes and the problems that ensue. The referring diagnoses were hypertrophic cardiomyopathy, congestive cardiomyopathy, coronary disease, and "unknown." In this context the exercise electrocardiograms, echocardiograms, and left heart studies are of special importance.

The exercise tests in this group of athletes are interesting. "Normalization" of T-wave changes on exercise may be a false indicator of normality and in fact represent considerable repolarization abnormality.[6] Nevertheless, in most cases of ischemic heart disease, abnormal S-T and T waves become more abnormal on exertion. Less is known about the response of the electrocardiogram to exercise in patients with hypertrophic cardiomyopathy. In a study of 30 patients with hypertrophic cardiomyopathy, McKenna et al.[7] did not observe T-wave normalization on exercise, but the tests were submaximal. In a smaller series of 10 patients[8] who were exercised for a thallium stress test the S-T and T waves either stayed the same or got worse. Therefore, T-wave normalization on exertion is not a common occurrence in hypertrophic cardiomyopathy.

As with the exercise tests, echocardiography is helpful, but is likely to raise fresh doubts if appearances in athletes are not known. Echocardiographic features in athletes have been thoroughly studied, the most typical finding being an increase in left ventricular cavity dimensions and wall thickness.[4,9] Sometimes, as in Patient 4, asymmetrical hypertrophy of the septum is noted, but the distinction of physiologic and other causes of hypertrophy from hypertrophic cardiomyopathy using ultrasound is not always easy.[10–13] For this reason we would have been unable either to exclude or to diagnose hypertrophic cardiomyopathy in Patients 3 and 4 on the echocardiographic features alone.

Catheterization studies were undertaken in this selected group of athletes because their ambitions, career prospects, and finances had been adversely affected by the diagnosis of organic cardiac disease. In those patients (Cases 3 and 4) whose echocardiogram showed the most increase in wall thickness, the ventricular angiogram also showed the most hypertrophy. In neither case was the ventricular cavity misshapen as in hypertropic cardiomyopathy, nor could an intraventricular gradient be provoked. Coronary arteriography excluded coronary artery disease in all 8 patients in whom it was performed, even in the patient with anterior wall dyskinesia.

Mechanism: The mechanisms underlying the development of these changes in athletes are speculative. Electrocardiograms of the "athlete's heart" type are also seen in nonathletes, but their frequency in highly trained subjects suggests that the changes are related to the ventricular hypertrophy caused by this training. The repolarization abnormalities need further explanation especially as only a small proportion of top athletes demonstrate gross electrocardiographic "abnormalities." Interest is currently focusing on geometric factors in the left ventricle.[14,15] Maybe the end result of hypertrophy, whatever the stimulus, is governed by the ventricular muscle fiber arrangement that the patient inherited. In this case, training constitutes the stimulus and only those athletes with a particular fiber arrangement will develop hypertrophy that is asymmetrical.

Reversibility: Not much is known about the reversibility of "athlete's heart" abnormalities. All our patients are still actively training, but 1 (Table I, Case 6) did show "normalization" of T waves after several months' inactivity. We are able to report on an Olympic standard walker in whom the diagnosis of hypertrophic cardiomyopathy was made on the basis of a palpable fourth sound, systolic murmur, large heart on chest radiograph, the electrocardiographic abnormalities suggesting left ventricular hypertrophy (Fig. 5), and an echocardiogram showing moderate systolic anterior motion of the mitral valve and a septum to left ventricular free wall thickness ratio of 1.5:1. Four years later, after total cessation of training, the echocardio-

gram is normal (septum to left ventricular posterior wall thickness ratio 1.1:1) and so is the electrocardiogram. No angiograms are available, but reversibility of the hypertrophy in this patient is evident.

Clinical implications: In the final reckoning, advice to asymptomatic athletes is a matter of personal belief. An athlete who can run a mile in 3 minutes 50 seconds is not normal. Is supernormality synonymous with abnormality, and, if so, is this abnormality likely to lead to sudden decreases in cardiac output or serious ventricular arrhythmias? There are several reports of sudden death during athletic performance.[16] Maron et al.[17] studied autopsy reports of young athletes known to have died suddenly. Twenty-nine cases were collected, in 22 of which death occurred during exertion. They emphasize the frequency with which organic disease is found, the most common being hypertrophic cardiomyopathy and idiopathic concentric left ventricular hypertrophy. It is difficult to relate these findings to the clinical examination of a specific athlete, because clinical data on the athletes who died were incomplete. Sudden death in nonathletes is also encountered, although of less dramatic impact. We make every attempt to exclude coronary disease and cardiomyopathy, but even if doubt remains we encourage resumption of athletics. We believe that the diagnosis of hypertrophic cardiomyopathy should depend on the unequivocal demonstration of hypertrophy, that the diagnosis should not be based entirely on the echocardiogram, and that no other cause of hypertrophy should exist because if it does, the attribution should be to this cause such as athletics or hypertension and not to hypertrophic cardiomyopathy.

Conclusion: Although the syndrome of athlete's heart is well known, some athletes develop more marked changes than are generally recognized and diagnostic confusion results in severe disadvantage to the patient. Under these circumstances every effort, including catheterization if necessary, must be made to establish normality. Coronary disease and congestive cardiomyopathy are readily excluded, but the differential diagnosis between "supernormality" and hypertrophic cardiomyopathy may be more difficult. We advise return to competitive sport unless we can make a confident, positive diagnosis of hypertrophic cardiomyopathy. This policy has not met with problems during 5 years of follow-up study.

Hypertrophic Nonobstructive Cardiomyopathy: A Precise Assessment of Hemodynamic Characteristics And Clinical Implications

YUZO HIROTA, MD, KOICHI FURUBAYASHI, MD, KIYOTAKA KAKU, MD, GEN SHIMIZU, MD, MASAYA KINO, MD, KEISHIRO KAWAMURA, MD, and TADASU TAKATSU, MD

A precise assessment of left ventricular function was performed in 20 patients with hypertrophic nonobstructive cardiomyopathy to elucidate the basic pathophysiology, and the data were compared with those in 22 normal subjects. Whereas end-diastolic pressure was high in those with cardiomyopathy, a more accurate index of preload, end-diastolic stress, did not differ from normal value. Afterload was about half the normal value. Both isovolumic indexes [peak positive dP/dt and (dP/dt)/DP_{40}] and ejection phase indexes of contractility (ejection fraction) were in the normal range; however, the end-systolic stress volume ratio was significantly reduced (43% of the normal value). Although the left ventricular minute work index was in the normal range, the unit muscle performance (minute work/mass) was very low (49%). An abnormality of left ventricular relaxation was demonstrated by low peak negative dP/dt (56%) and prolonged time constant T (191%), and a stiff left ventricle was demonstrated by a high diastolic elastic stiffness constant (129%).

These observations suggest that the contraction of a unit muscle is inappropriate to produce an adequate contraction of the whole ventricle, and that hypertrophy might be an adaptive process to maintain normal systolic function by increasing mass and reducing afterload.

Hypertrophic cardiomyopathy has been reported to be characterized by impaired diastolic function and well-maintained systolic function.[1-3] Pump function and indexes of contractility are normal or supernormal in the majority of patients, and a hypercontractile state in the obstructive type of this disease has been emphasized, based on the facts that the intraventricular pressure gradient is increased by the administration of positive inotropic agents and preload or afterload reducing agents,[3-5] or both, and that salutary effects can be achieved by the administration of negative inotropic agents or augmentation of preload and afterload.[1,3,4]

Cardiac performance, however, consists of complex integrations of preload, afterload, contractility, relaxation, and compliance,[6-8] and normal systolic function as such does not mean that contractility is normal. Some investigators have objected to the concept of "hypercontractile state" in this disease, based on the observation of a poorly contracting interventricular septum[9,10] and the analysis of left ventricular function.[11,12] A serious question of whether contractility of the diseased heart is normal can be raised, based on a relatively characteristic histologic feature—bizarre-shaped and disarrayed myocardial cells—which has been known since Teare[13] described the first 8 cases of this disease.

Although there have been numerous reports about this disease, most recent ones are concerned with the echocardiographic findings, and studies on the basic

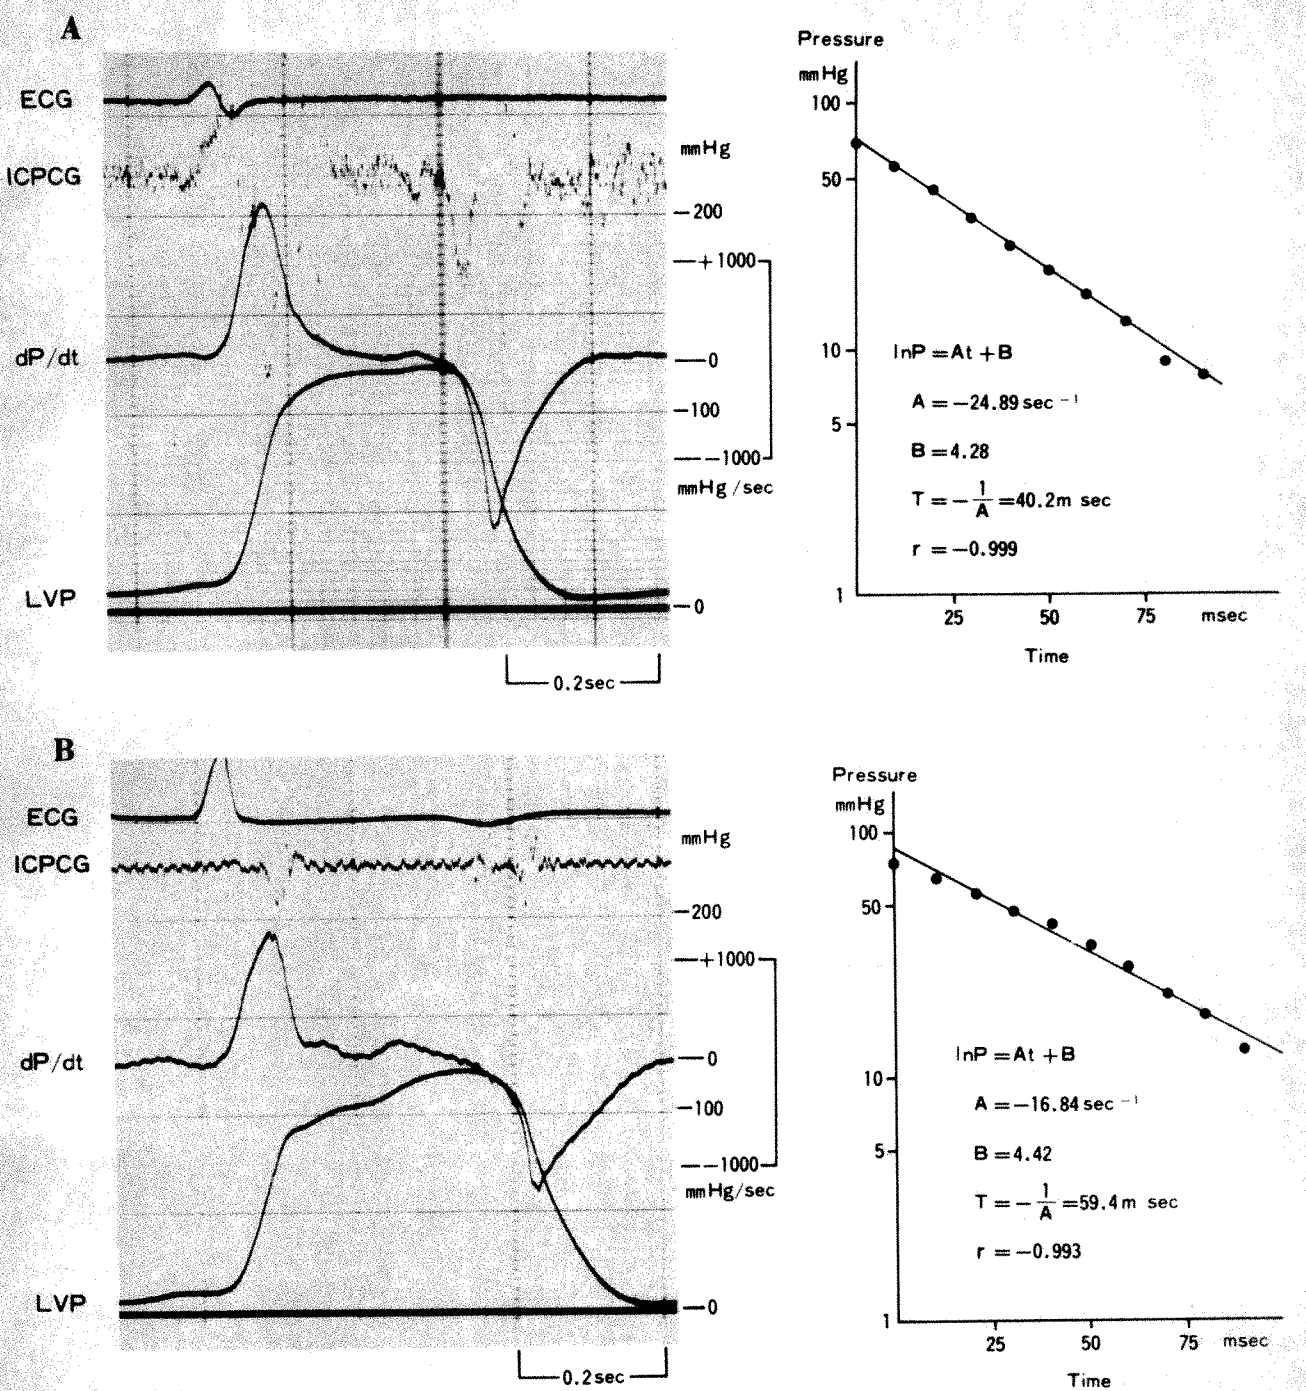

FIGURE 1. Two representative left ventricular pressure tracings. **A,** from a 42 year old man in the normal group and **B,** from a 46 year old man with apical hypertrophy. Left ventricular pressure during the isovolumic relaxation period is plotted by semilogarithmic scale on the **right** of each panel to obtain the time constant of the pressure decrease (the time constant T). The characteristics of hypertrophic cardiomyopathy, that is, low value of the maximal rate of the pressure decrease (peak negative dP/dt) and prolonged time constant T are demonstrated in **B.** A = the gradient of pressure against time; B = the intercept of pressure at time 0; ECG = electrocardiogram; ICPCG = intracardiac phonocardiogram; lnP = natural logarithm of pressure; LVP = left ventricular pressure.

pathophysiology have been limited to the obstructive type.[3] Medical and surgical treatments have focused only on this type of the disease, and the management of the nonobstructive type has been neglected even in the most recent textbook.[3] This is due partly to the fact that the basic pathophysiology of the nonobstructive type is still obscure.

This study was undertaken to evaluate left ventricular function precisely in hypertrophic nonobstructive cardiomyopathy using high fidelity pressure tracings and quantitative analyses of cineangiography, and to elucidate the basic pathophysiology in the hope that some fundamental approaches to the treatment of this disease might be established.

TABLE I Patient Groups, Left Ventricular and Aortic Pressures, Cardiac Index, and Systemic Vascular Resistance (SVR)

Group	Patients (n)	Sex	Age (yr)	HR (beats/min)	Pressure (mm Hg) LVS	LVED	AOM	AOD	CI (liters/min/m²)	SVR (dynes s cm⁻⁵)
HCM	20	16M 4F	39 ±13	68 ±9	115 ±13	14.2* ±6.7	85† ±11	99 ±14	3.03 ±1.05	1,469 ±516

All data are expressed as mean ± 1 standard deviation of the mean.
* $p < 0.001$ compared with values in normal subjects. † $p < 0.05$ compared with values in normal subjects.
AOD = aortic dicrotic pressure; AOM = mean aortic pressure; CI = cardiac index; HCM = hypertrophic cardiomyopathy; HR = heart rate; LVED = left ventricular end-diastolic pressure; LVS = left ventricular systolic pressure; NS = normal subjects.

Methods

Study group: Among 30 patients with hypertrophic cardiomyopathy who underwent diagnostic cardiac catheterization between April 1976 and August 1980, 20 are the subjects of this study. Ten patients were excluded; 2 had the obstructive type, 1 had concomitant coronary artery disease, and high fidelity pressure tracings or cineangiograms of good quality could not be obtained in 7 cases. The diagnosis was established according to the criteria of the Study Group of Idiopathic Cardiomyopathy of Japan,[14] after modification of Goodwin's criteria.[1] Twenty-two patients who underwent catheterization for various reasons during the same period and were found to have no significant heart disease served as control subjects. Precise descriptions of the procedure of catheterization have been reported from this laboratory.[15]

Study procedure: Cardiac catheterization was performed using the brachial approach, in the fasting state and premedication with 2 mg of diazepam and 500 mg of bromovalerylurea orally, or diazepam alone, 5 mg orally. Right heart pressures were recorded with a fluid-filled system. Cardiac output was measured by the Fick or the thermodilution method. Left heart pressures were recorded in each case with a Mikro-tip® angiocatheter (model PC-471 or 481, Millar Instruments) with simultaneous recording of the first derivative of the pressure (dP/dt). Zero level was calibrated electrically by a transducer control unit (model TCB-100, Millar Instruments) before insertion of the catheter, and zero shift was adjusted at the mid-chest position through the fluid-filled system of the same catheter. Photographic recordings were obtained at paper speeds of 100 and 200 mm/s, using an 8 channel optical recording system (model 4588D, Hewlett-Packard). Five consecutive complexes in cases of normal sinus rhythm and 10 consecutive complexes in cases of atrial fibrillation (1 case in the cardiomyopathy group) were averaged for the determinations of pressure and the data derived from pressure tracings.

Angiography: Cineangiography was performed just after the pressure recordings were taken, using the same catheter in a 30° right anterior oblique projection. Thirty to 45 ml of contrast material (Angioconray®) was injected in 3 seconds by a power injector. Films were exposed at a rate of 60 frames/s with a 35 mm cine camera (Arritechno 35) mounted on a 25 cm image intensifier (Cardoscope U, Siemens). A pigtail catheter was inserted from the femoral artery, and the intraventricular pressure gradient was measured at rest and after infusion of isoproterenol, Valsalva maneuver, and postextrasystolic potentiation in all patients with hypertrophic

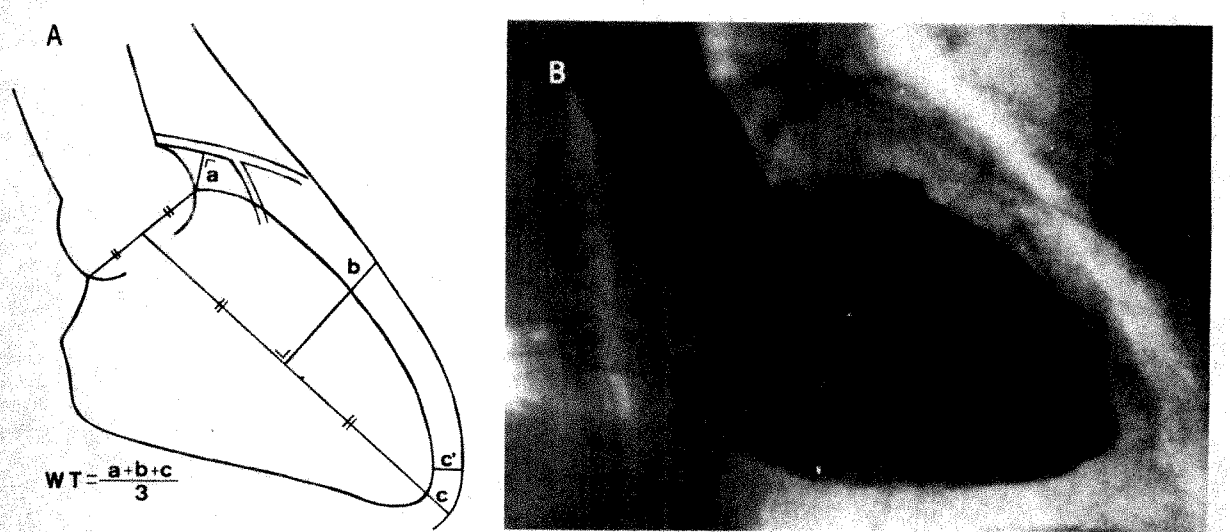

FIGURE 2. Schematic description of the calculation of the wall thickness from a drawing of the cineangiogram (**A**) and a representative cineangiogram (**B**). **A**, as disproportionate hypertrophy is a very common finding in hypertrophic cardiomyopathy, 3 points of the free wall were measured in this study at end-diastole, midsystole, and end-systole to calculate wall thickness (WT), mass, and stress. The vertical distance from the base to the left main coronary artery or the anterior descending artery (a), wall thickness at the mid-point of the anterior free wall (b), and the distance from the apex to the outer silhouette (c) were measured and averaged. As point c was difficult to identify on some occasions, the nearest well-identified point (c′) was used in such cases.

cardiomyopathy. Coronary cineangiograms were performed with the Sones' technique in all patients with hypertrophic cardiomyopathy and in the majority of normal control subjects, and were recorded in multiple projections using a 17 cm image intensifier.

Data analyses: *Two isovolumic phase indexes of contractility*, that is, the maximal rate of rise of left ventricular pressure (peak positive dP/dt) and dP/dt at the developed pressure 40 mm Hg divided by developed pressure 40 mm Hg ($[dP/dt]/DP_{40}$), and 2 indexes of relaxation, that is, the maximal rate of left ventricular pressure fall (peak negative dP/dt) and the time constant of the pressure fall (the time constant T),[16] were calculated from the pressure tracing and its first derivative (Fig. 1).

Left ventricular volumes, the short and long axes, and wall thickness were calculated at end-diastole, mid-systole, and end-systole by the area-length method of Dodge et al.,[17] using a semicomputerized system (combinations of a motion analyzer, a sonic graph pen, a microcomputer, and a graphic printer: Cardias GP 2000, Nac). There is a certain limitation in the assessment of wall thickness and the data derived from the wall thickness on cineangiography in patients with hypertrophic cardiomyopathy, because disproportionate hypertrophy such as asymmetric septal hypertrophy is a very common finding in this disease. To avoid such an inherent error as much as possible, wall thickness was measured at the base, the mid-anterior portion, and the apex in all cases (Fig. 2), and these 3 values were averaged for the calculations of wall thickness, mass, and stress. Ejection fraction (EF) was calculated by the formula: EF = EDV − ESV/EDV, where EDV is the end-diastolic volume and ESV is the end-systolic volume.

Mid-wall circumferential stress (σ) was calculated using an ellipsoid model of Mirsky's formula[18]: $\sigma = (Pb/h)[1 - (h/2B) - (B^2/2A^2)]$, where P is the pressure, A and B are the minor and major radii to the mid wall, respectively, and h is the averaged wall thickness. End-diastolic stress (σed) was calculated from the end-diastolic frame of the cineangiography and end-diastolic pressure for the determination of an accurate index of preload.[6,19] For the assessment of afterload, midsystolic stress was measured from the systolic pressure and the midsystolic frame of the cineangiogram, because the midsystolic stress has been reported to correlate significantly ($r = 0.97$) with mean systolic stress.[20] End-systolic stress was obtained from the aortic dicrotic pressure and the end-systolic frame of the film for the assessment of the contractile state by means of the end-systolic volume and pressure or stress relation.[21–25] Although the pressure was recorded during the cineangiographic procedure in all cases, the pressures just before the procedure were employed for the calculations of stress, because significant pressure distortions were almost always present because of the Valsalva maneuver during cineangiography.[12]

Left ventricular (LV) mass was calculated by the formula of Rackley et al.[26]: LV mass = $\{4/3\pi[(D + 2h)/2]^2[(L + 2h)/2] - V\} \times 1.05$, where D is the short axis, L is the long axis, h is the wall thickness, and V is the volume at the end-diastole.

The following formulas were employed for the calculation of resistance and ventricular performance: SVR = [(mean AOP − mean RAP) × k]/CO(dynes s cm^{-5}); LVMWI = (mean AOP − LV edp) × CO/BSA × 13.6 (kg·m/min per m^2), and left ventricular unit muscle minute work = LVMW/LV mass (g·m/min per g), where SVR is systemic vascular resistance, k is a constant, CO is cardiac output, AOP is aortic pressure, RAP is right atrial pressure, LVMWI is left ventricular minute work index, BSA is body surface area, and LVMW is left ventricular minute work.

TABLE II Data Derived From Left Ventricular Cineangiography

Group	LV Volume (ml/m^2) EDVI	ESVI	Mean WT at ED (mm)	LV Mass Index (g/m^2)
HCM	75 ±14	25 ±8	13.4* ±3.5	147† ±87
NS	69 ±20	25 ±9	8.8 ±1.5	77 ±29

All data are expressed as mean ± 1 standard deviation of the mean.

* $p < 0.001$ compared with values in normal subjects. † $p < 0.01$ compared with values in normal subjects.

ED = end-diastole; EDVI = end-diastolic volume index; ESVI = end-systolic volume index; LV = left ventricular; WT = wall thickness. Other abbreviations as in Table I.

For the assessment of diastolic compliance, the diastolic elastic stiffness constant (K) was evaluated by the method of Mirsky[27]: End-diastolic elastic stiffness (g/cm^2) = Kσed + Ce, where Ce is the contractile element, $K = \delta(\alpha Ved) + (1 + \gamma)/(1 - h/2BC_1)$, $\gamma = (\alpha_1 Vw - \beta_1 V)/(\alpha_2 Vw + \beta_2 V)$, $\delta = [2 + (\gamma h/B)][1 + (h/2B) + (h^2/4B^2)] + [1 + (\gamma h/2A)][1 + (h/2A)]$, $\alpha_1 = 3 - (h/B) - (h/2A) + (h^2/2B^2)$, $\beta_1 = (h/A) + (2h/B)$, $\alpha_2 = (h/B)[1 - (h/2B) + (h^2/4B^2)] + (h/2A)[1 - (h/2A)]$, $\beta_2 = (h/B)[2 + (h^2/2B^2)] + (h/A)$, $C_1 = 1 - (B^2/2A^2)$, and $Ved = \ln(2.33\ Ped)$; where Vw is the volume of the left ventricular muscle mass, V is the ventricular volume, A and B are the short and long axes, respectively, and h is the wall thickness.

Statistics: The unpaired Student's *t* test was employed for the statistical analyses in comparing the group of patients with hypertrophic nonobstructive cardiomyopathy and the group of normal subjects. Data are presented as mean ± standard deviation.

Results

Clinical features: Among 20 patients with cardiomyopathy, 15 satisfied the echocardiographic criteria of asymmetric septal hypertrophy,[28] 2 were considered to have apical hypertrophy[29] on 2-dimensional echocardiography as well as cineangiography, and 3 showed concentric hypertrophy by these methods. All patients had no pressure gradient in the ventricle at rest, but 30 to 55 mm Hg pressure gradients were elicited after isoproterenol infusion in 3 patients with asymmetric septal hypertrophy. Three patients were symptom-free, 11 had atypical chest pain, mild dyspnea on exertion, palpitation or dizzy spells, or both, and they were considered to be in New York Heart Association[30] functional Class II. Six patients had severe symptoms of dyspnea, chest pain, and frequent episodes of paroxysmal atrial fibrillation, and 2 of them exhibited persistent atrial fibrillation during the observation period of 1 to 2 years after catheterization. One died suddenly after running 50 meters to get on a bus, and 1 had 2 documented episodes of ventricular fibrillation. There were no differences in age and sex distribution in the patients with cardiomyopathy and normal subjects (Table I).

Hemodynamic findings: By conventional measurements of pressure and cardiac output, left ventricular end-diastolic pressure was elevated in a majority of the patients with cardiomyopathy compared with

TABLE III Left Ventricular Minute Work Index, a Unit Muscle Minute Work, and End-Systolic Pressure/Volume and End-Systolic Stress/Volume Ratios

Group	LVMWI (kg·m/min/m²)	LVMW/LV Mass (g·m/min/g)	AOD/ESVI (mm Hg/ml/m²)	σes/ESVI (g/cm²/ml/m²)
HCM	3.02 ±1.30	27.5* ±19.2	4.52 ±2.07	2.82* ±1.54
NS	3.81 ±1.28	56.4 ±29.5	4.92 ±2.87 (n = 20)	6.50 ±2.56 (n = 20)

All data are expressed as mean ± 1 standard deviation of the mean.
* p <0.001 compared with values in normal subjects.
LVMW = left ventricular minute work; LVMWI = left ventricular minute work index; NS = normal subjects; σes = end-systolic stress. Other abbreviations as before.

normal subjects (mean 14.2 ± 6.7 versus 8.4 ± 3.4 mm Hg, p <0.001), with slightly lower mean aortic pressure (85 ± 11 versus 93 ± 11 mm Hg, p <0.05) (Table I). The cineangiographic characteristics of hypertrophic cardiomyopathy were a thick wall (1.34 ± 0.35 versus 0.88 ± 0.29 cm, p <0.001) and increased wall mass (147 ± 87 versus 77 ± 29 g/m², p <0.01) (Table II). Although cardiac index and left ventricular minute work index were in the normal range, the unit muscle performance estimated by left ventricular minute work/mass was about half the normal value (27.5 ± 19.2 versus 56.4 ± 29.5 g·m/min per g, p <0.001) (Tables I and III). Whereas left ventricular end-diastolic pressure was high in the group with cardiomyopathy, a more accurate index of preload, end-diastolic stress, did not differ from that of normal subjects. Afterload to the left ventricle was about half the normal value (131 ± 53 versus 270 ± 70 g/cm², p <0.001). Both isovolumic phase and ejection phase indexes of contractility were in the normal range (Table IV). A relaxation abnormality was demonstrated by lower peak negative dP/dt (1,079 ± 329 versus 1,923 ± 440 mm Hg/s, p <0.001) and prolonged time constant T (63 ± 23 versus 33 ± 8 ms, p <0.001) (Table IV). The diastolic elastic stiffness constant was significantly elevated (20.0 ± 3.8 versus 15.5 ± 2.7, p <0.001), which suggests that the left ventricle is less compliant in this disease.

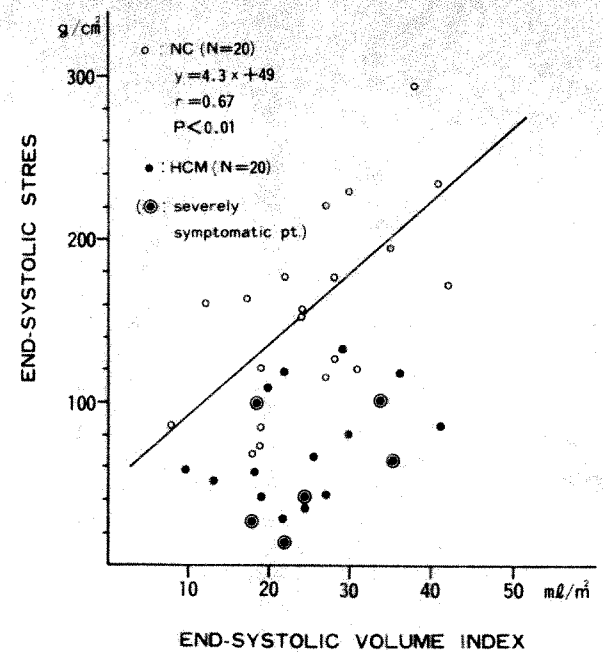

FIGURE 3. Relation between end-systolic stress and end-systolic volume index. A significant positive correlation was present between these 2 variables among the 20 normal control (NC) subjects (**open circles**) (r = 0.67, p <0.01). This observation suggests that end-systolic volume is dependent on end-systolic stress or vice versa even at rest in the normal human left ventricle. Although end-systolic volume in the 20 patients with hypertrophic cardiomyopathy (HCM) did not differ from the normal value, end-systolic stress was significantly decreased (p <0.001), and the end-systolic stress/volume ratio was shifted downward in the majority of patients (**closed circles**). This phenomenon is more apparent in 5 of the 6 severely symptomatic patients (pt.) identified as **double circles.**

Left ventricular end-systolic pressure-volume and stress-volume relations were obtained for the evaluation of the contractile state (Table III). End-systolic pressure and volume did not differ from normal values, and hence the pressure-volume ratio also did not differ between the two groups. Although there was no significant correlation between end-systolic pressure and volume among normal subjects, a significant positive correlation was present between end-systolic stress and volume in this group (Fig. 3). The end-systolic stress-volume relation was shifted downward in the cardio-

TABLE IV Indexes of Preload, Afterload, Contractility, Relaxation, and Compliance

Group	Stress (g/cm²) σed	σms	σes	EF (%)	Peak (+) dP/dt (mm Hg/s)	Peak (−) dP/dt (−mm Hg/s)	(dP/dt)/DP$_{40}$ (s^{-1})	T (ms)	K
HCM	23.8 ±11.5	131* ±53	65* ±34	67.8 ±7.2	1,510 ±343	32.9 ±7.0	1,079* ±329	63* ±23	20.0* ±3.8
NS	24.7 ±9.6	270 ±70	155 ±59	65.2 ±7.2	1,681 ±413	31.4 ±5.3	1,923 ±440	33 ±8	15.5 ±2.7

All data are expressed as mean ± 1 standard deviation of the mean.
* p <0.001 compared with values in normal subjects.
EF = ejection fraction; (dP/dt)/DP$_{40}$ = the rate of left ventricular pressure rise at developed pressure 40 mm Hg divided by developed pressure 40 mm Hg; K = diastolic elastic stiffness constant; peak (+) and (−) dP/dt = maximal rate of left ventricular pressure increase and decrease; T = time constant of the left ventricular pressure decrease; σed = end-diastolic stress as an index of preload; σms = mid-systolic stress as an index of afterload. Other abbreviations as before.

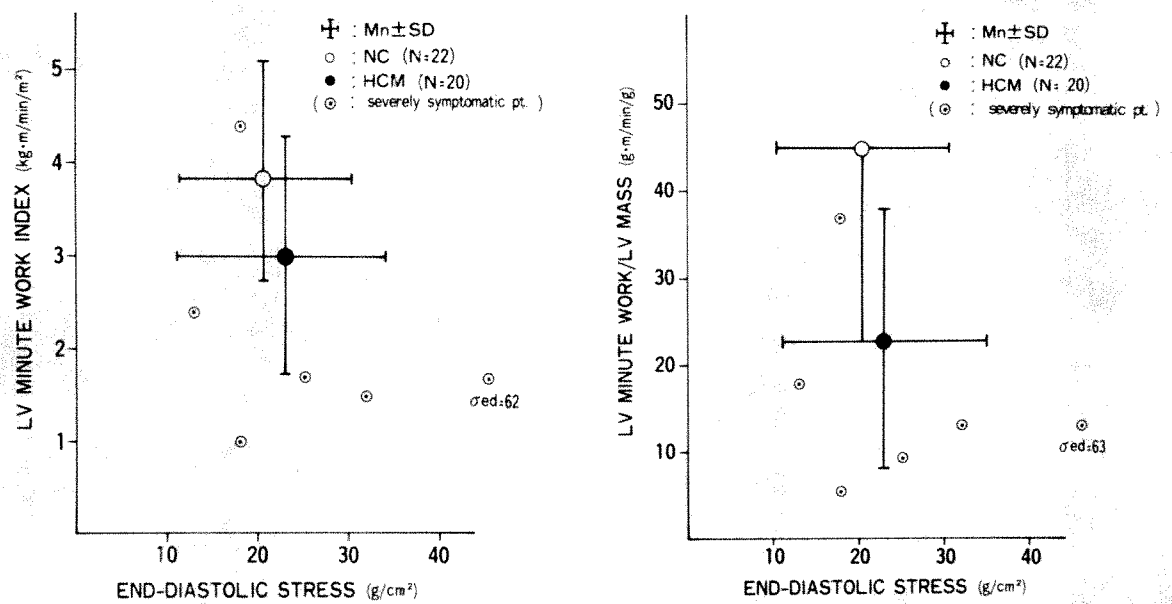

FIGURE 4. Relations between left ventricular minute work index and preload (**left**), and between a unit muscle performance and preload (**right**). **Left,** both left ventricular minute work index and preload (end-diastolic stress = σed) did not differ in patients with hypertrophic cardiomyopathy and normal subjects, indicating that patients with this disease maintain normal systolic pump function. However, the left ventricular performance in 4 of the 6 severely symptomatic patients was clearly below normal. **Right,** left ventricular unit muscle performance estimated by minute work/mass was about half the normal value ($p < 0.001$). Low performance with the same level of preload suggests that the contraction of a single muscle makes an inappropriate contribution to the contraction of the whole left ventricle. Abbreviations as in Figure 3.

myopathy group, and this ratio was significantly lower than the normal value (2.82 ± 1.54 versus 6.50 ± 2.56 g/cm²/ml per m², $p < 0.001$) (Table II).

Discussion

It is well known that cardiac performance depends on complex integrations of preload, afterload, contractility, relaxation, and compliance,[6–8] and precise assessments of these indexes are necessary for the elucidation of the basic pathophysiology of a given disease. Although recent technologic advances make it possible to obtain accurate indexes of these variables when an appropriate combination of high fidelity pressure tracing, high quality cineangiography, and computer system is employed, the majority of recent studies on hypertrophic cardiomyopathy are limited to echocardiographic observations; the basic pathophysiology of this disease is still obscure. This may be due partly to the difficulty of assessing left ventricular wall thickness and volume, and the data derived from them, because asymmetric hypertrophy of the wall and cavity obliteration are characteristic findings of this disease. Recognizing these inherent technical problems, this study was carried out in the hope that the pathophysiology of hypertrophic cardiomyopathy could be elucidated by analyzing data from an adequate number of patients. Two patients with the obstructive type were excluded from this study because left ventricular pressure was not uniform and cavity obliteration was more severe than in the nonobstructive type.

Indexes of systolic ventricular performance: In patients with cardiomyopathy, left ventricular systolic pressure, cardiac output, systemic vascular resistance, left ventricular volume, and ejection fraction did not differ from those in normal subjects. Isovolumic phase indexes of contractility were also in the normal range. This observation indicates that the systolic function is normal when it is considered as a pump. Cineangiographic characteristics were increased wall thickness and mass. As 15 of the 20 patients had echocardiographic evidence of asymmetric septal hypertrophy, wall thickness and mass calculated from the 3 points of the anterior wall may still be underestimated, and therefore stress may be overestimated.

Although end-diastolic pressure has frequently been used as an index of preload, stress at end-diastole is preferable when 2 groups of different compliance are compared.[6,19] Normal systolic pump function is demonstrated by the relation between preload and performance (Frank-Starling's relation). However, as these patients maintain normal systolic function with increased mass, a serious question is schematically shown by the relation between left ventricular unit muscle performance and preload (Fig. 4).

Afterload is defined as stress during systole, and mean systolic stress is preferable for the accurate evaluation of afterload.[6] It is time-consuming to obtain mean systolic stress, however, because it requires simultaneous measurements of ventricular pressure, volume, and wall thickness of each frame of the cineangiogram during the whole systole. Mid-systolic stress was employed here as an index of afterload because we found that this is almost identical to mean systolic stress ($r = 0.97$).[20] It was about half the normal value in hypertrophic cardiomyopathy. It is well known that the ejection phase indexes of contractility are strongly af-

fected by afterload.[6,10] Looking at the relation of these two variables, a normal ejection fraction in this disease seems to be the result of low afterload (Fig. 5). Markedly low peak systolic stress in hypertrophic cardiomyopathy has been reported by Hood et al.[31] and Gaasch et al.,[11] and the latter authors postulated depressed contractility or low afterload in this disease.

Recently, Suga and Sagawa[21] and their associates[22] proposed the end-systolic pressure-volume relation as a new index of contractility. Although this relation is independent of loading conditions, it is not preferable for the comparison of 2 different groups or diseases,[23–25] and the relation between end-systolic stress and volume is more suitable for this purpose.[23,25] Takahashi et al.[25] demonstrated a normal contractile state in mild left ventricular hypertrophy and a depressed contractile state in severe left ventricular hypertrophy associated with systemic hypertension. Among our 20 normal subjects, the relation between end-systolic stress and end-systolic volume index showed a significant correlation, and that of the patients with hypertrophic cardiomyopathy was shifted significantly downward, suggesting a depressed inotropic state in this disease.

From these observations, the following hypothesis can be derived: When contraction of a unit muscle is inappropriate to produce an adequate contraction of the whole ventricle, hypertrophy might be a "compensatory mechanism" to maintain normal systolic function. Although eccentric and concentric hypertrophy are generally considered adaptive processes for volume and pressure overload, respectively, hypertrophy in hypertrophic cardiomyopathy may be another form of compensatory mechanism.

Diastolic ventricular performance: Impaired relaxation of the left ventricle in this disease was emphasized early by Goodwin.[1] Low peak negative dP/dt was reported by Toshima et al,[32] and we[15] reported severe relaxation disturbance using peak negative dP/dt and the time constant T. Subsequent cases also showed a prolonged time constant T and low peak negative dP/dt. Although the genesis and clinical significance of this relaxation abnormality is not clear, it seems to be an important factor for the early diastolic filling disturbance because it takes about 3 times of the time constant T for the left ventricle to relax completely[33]; moreover, an early diastolic filling disturbance was reported by Matsuo et al.,[34] who measured diastolic mitral valve flow by means of the pulsed Doppler method. Acute symptomatic deterioration with the sudden onset of tachyarrhythmia is frequently observed in these patients. Whereas this phenomenon has been explained by inadequate filling of the stiff ventricle due to sudden loss of atrial contraction,[3] impaired relaxation and hence inadequate early diastolic filling may also play an important role in symptomatic deterioration with the appearance of tachyarrhythmias.

Reduced compliance or stiff left ventricle has been frequently emphasized by many investigators.[1–3,11,12,18] In the present study a high diastolic stiffness constant was demonstrated, as was reported by Mirsky.[27] In

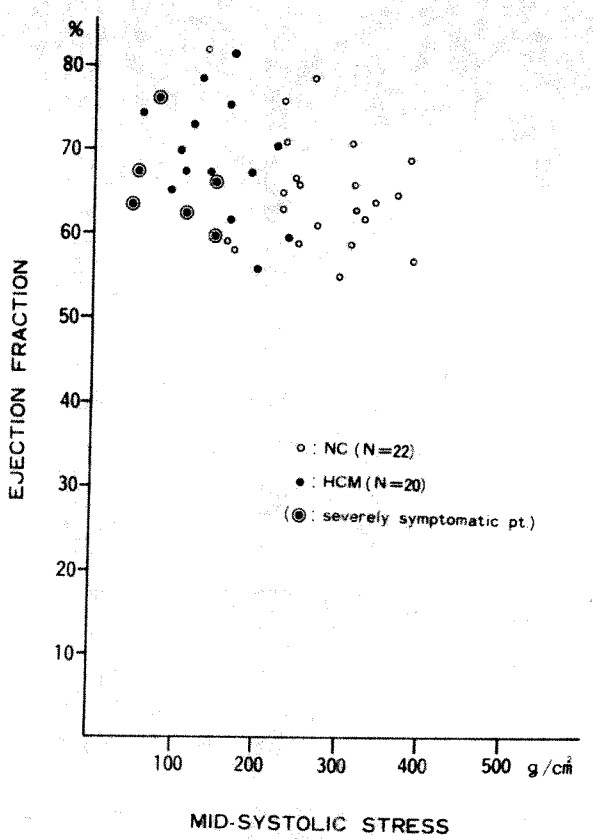

FIGURE 5. Relation between afterload and ejection fraction. Whereas there was no significant difference in ejection fraction between patients with hypertrophic cardiomyopathy and normal subjects, afterload was about half the normal value in this disease ($p < 0.001$) and this relation shifted to the left. This observation suggests that normal ejection fraction is maintained with increased mass and reduced afterload. The phenomenon was most prominent among 4 of the 6 severely symptomatic patients. Abbreviations as before.

contrast to reduced afterload in hypertrophic cardiomyopathy, afterload was normalized with increasing wall thickness in systemic hypertension.[35] Prolonged relaxation and stiff left ventricle was also demonstrated in these patients,[15,36] suggesting that concentric hypertrophy itself can result in prolonged relaxation and stiff ventricle. The degree of hypertrophy, prolonged relaxation, and stiff ventricle in systemic hypertension, however, were less severe than in hypertrophic cardiomyopathy.[36] Therefore, the important question of whether these diastolic abnormalities of hypertrophic cardiomyopathy are attributable to increased wall thickness as such or due partly to the characteristics of this disease remains unsolved.

Clinical implications: Among 20 patients with hypertrophic nonobstructive cardiomyopathy, 6 had severe symptoms. Left ventricular end-diastolic pressure was greatly elevated in 5 of these 6 patients (17 to 32 mm Hg), and the remaining patient (9 mm Hg) has had repeated episodes of paroxysmal atrial fibrillation and dyspnea during a follow-up period of 3 years, suggesting that end-diastolic pressure and hence left atrial pressure was elevated. Looking at the relation between preload and performance (Fig. 4), it is apparent

that the ventricular function in 4 of these patients was depressed. Although contractility indexes of these 6 patients were all within the normal range, the depressed systolic function in 5 of them also became apparent when the relations between afterload and ejection fraction and between end-systolic stress and volume were considered.

Several important implications for the management of patients with hypertrophic cardiomyopathy can be derived from this analysis. One patient died immediately after running to get on a bus. Whereas syncope after strenuous exercise and with the administration of preload or afterload reducing agents, or both, has been emphasized in patients with the obstructive type,[3,5] the same precautions must be taken in patients with the nonobstructive type. Although left ventricular end-diastolic pressure is elevated in the majority of these patients, preload is maintained in the normal range because of the thick-walled ventricle, and reduction of preload may not only produce syncope but also be life-threatening on some occasions. It is apparent from the Frank-Starling's curve that the sudden reduction of preload due to peripheral pooling of blood after strenuous exercise may result in life-threatening low cardiac output.

Although beta-adrenergic blocking agents are occasionally administered for the treatment of chest pain or arrhythmias, we observed acute development of dyspnea during the administration of propranolol in 3 patients in this study group as well as in 2 patients with the obstructive type who were not included in this study. The administration of such drugs may result in sudden elevation of end-diastolic pressure with reduction in cardiac output. Therefore, the administration of such drugs must be carried out with great caution.

Acknowledgment

We express our great appreciation to Professor Walter H. Abelmann, MD, of the Harvard Medical School and Professor Chuichi Kawai, MD, of the Faculty of Medicine, Kyoto University, for their critical review of this paper and pertinent advice.

The Heart and Cardiac Conduction System in Polymyositis-Dermatomyositis: A Clinicopathologic Study Of 16 Autopsied Patients

HELEN M. HAUPT, MD and GROVER M. HUTCHINS, MD

We reviewed the clinical records of 16 patients with polymyositis-dermatomyositis syndromes autopsied at The Johns Hopkins Hospital to determine the nature and extent of cardiac involvement and its correlation with the severity of disease as a whole. The adult patients ranged in age from 32 to 84 years (average 56); the 2 children were aged 2 and 10 years. The duration of disease ranged from 1 to 72 months (average 21). Seven patients had dermatomyositis, 5 had dermatomyositis with malignancy, 2 had childhood dermatomyositis, and 2 had an overlap syndrome. Seven patients had clinical evidence of congestive heart failure, 4 of whom had microscopic evidence of myocarditis. Two patients had bundle branch block; in 1 there was direct involvement of the conduction system by myositis and contraction band necrosis. Evidence of active myocarditis was present in 4 patients (25%); all had congestive failure. Focal myocardial fibrosis was present in 4 patients. Vascular alterations were present in the coronary arteries in 5 patients (31%). Three had active vasculitis, 1 had intimal proliferation, and 1 had medial sclerosis with calcification. All patients with active myocarditis had skeletal muscle involvement. Nine patients had myositis without myocarditis. There was no correlation of overall severity of the disease with the presence or absence of active myocarditis. The present study shows that cardiac involvement may be common in polymyositis; congestive failure or conduction abnormalities arising in this setting may be indicative of myocarditis.

Polymyositis may involve the heart.[1-17] The reported clinical manifestations include atrial and ventricular arrhythmias,[1,3,5-7,11,17] nonspecific ST-T wave changes,[3,4,6,7,11] conduction abnormalities,[1,3,5-7,11-15,17] left axis deviation,[6] congestive heart failure,[3,7,9,11,12] mitral valve prolapse,[17] and a hyperkinetic state.[16,17] Once thought relatively rare, clinical evidence of cardiac involvement in patients with polymyositis studied noninvasively was recently reported in as many as 52% of those with electrocardiographic abnormalities, 65% of those with mitral valve prolapse, and 76% of all those with cardiac abnormalities.[17] Pathologic studies have documented active myocarditis,[9-11] myocardial[8,11,12] and conduction system fibrosis,[12,13,15] vascular abnormalities,[11] and pericarditis.[10] The correlation of cardiac manifestations in polymyositis with overall severity of the disease in other organ systems is unknown. We reviewed the clinical and pathologic features of 16 autopsied patients with polymyositis to determine whether such a relation exists and to better define the clinical manifestations that may be used as indexes of myocardial involvement in polymyositis.

Methods

Study cases: All cases of patients with a diagnosis of polymyositis or dermatomyositis listed in the autopsy files of The Johns Hopkins Hospital from 1889 through 1980 were reviewed. Sixteen cases satisfying the diagnostic criteria of Bohan and Peter[1] were included in the study. These are: (1) symmetrical progressive proximal muscle weakness; (2) muscle biopsy evidence of myositis; (3) elevation of serum skeletal muscle enzymes, particularly creatine kinase, but including aldolase, glutamic oxalacetic and pyruvic transaminases, and lactate dehydrogenase; (4) electromyographic evidence of myositis; and (5) dermatologic findings, including heliotrope rash, periorbital edema, erythematous dermatitis

on the dorsum of the hands (Gottron's sign), and involvement of the knees, elbows, and medial malleoli as well as the face, neck, and upper trunk. The confidence limits were defined as: definite, 3 or 4 criteria (with rash) for dermatomyositis, or 4 criteria (without rash) for polymyositis; probable, 2 criteria (with rash) for dermatomyositis, or 3 criteria (without rash) for polymyositis; and possible, 1 criterion (with rash) for dermatomyositis, or 2 criteria (without rash) for polymyositis.

The clinical records of each patient were reviewed for age, sex, race, duration of disease, and presence and duration of treatment. Clinical manifestations including muscle weakness, serum enzymes (creatine kinase, aldolase, glutamic oxalacetic transaminase, glutamic pyruvic transaminase, and lactic acid dehydrogenase), diagnostic muscle biopsy, and electromyographic results were recorded. Associated findings including dysphagia, Raynaud's phenomenon, arthritis, pulmonary disease, and malignancy were noted.

Each case was classified into 1 of the following 5 categories of polymyositis[1,3,4]: (I) polymyositis; (II) dermatomyositis; (III) polymyositis or dermatomyositis associated with malignancy; (IV) childhood polymyositis or dermatomyositis with vasculitis; or (V) polymyositis or dermatomyositis with associated connective tissue disorder (overlap group). Electrocardiographic findings, clinical evidence of congestive heart failure, mitral valve prolapse, or hyperkinesia were recorded. No patient autopsied before 1961 met the diagnostic criteria.[1] Nine patients were autopsied in the 1960s, 4 in the 1970s, and 3 in the 1980s. Serum skeletal muscle enzyme determinations were available for 12 patients. Of the 4 in whom they were not, 2 died in the 1960s, 1 in the 1970s, and 1 in the 1980s. Electromyographic results were available in only 1 patient. In the others the presence of muscle weakness was established by physical examination. A total of 3 echocardiograms were performed, all in the same patient. Data on 12 lead electrocardiograms were available for 10 patients. Of those for whom this information was unavailable, 4 were autopsied in the 1960s and 2 in the 1970s.

Pathologic manifestations: The gross specimen of the heart was reviewed in 10 cases. Otherwise the cardiac data were taken from descriptions and measures made by the prosector at autopsy. Pathologic determinations on the heart included: heart weight, valve dimensions, chamber volumes, myocardial thickness, assessment of valvular alterations, pericardial inflammation, presence and extent of myocardial fibrosis, presence of infarcts and degree of atherosclerotic narrowing of the coronary arterial tree, and evidence of vasculitis. The conduction systems were studied by serial histologic sectioning in 11 patients using a standard technique.[18,19] Briefly, the sinoatrial node area and a large block containing the approaches and the atrioventricular node, His bundle, and proximal right and left bundles were removed. The blocks were serially sectioned at 8 μm and every 15th section was retained. Alternate slides were stained with hematoxylin and eosin, Verhoeff-van Gieson elastin stain, and other methods as indicated. At least 150 slides were prepared on each conduction system studied.

Hematoxylin and eosin-stained microscopic sections of the following organs were examined in each case: heart (average 6, exclusive of conduction system), lung (average 8), and muscle (average 6). Skin (average 2) and gastrointestinal tract (average 6) were reviewed when available. The extent, severity, and degree of activity of involvement was assessed in all heart, muscle, and skin microscopic sections according to accepted histologic criteria.[2,4] Lung and gastrointestinal sections were examined for microscopic findings suggestive of overlap syndromes.

Results

Patient Profile

Sixteen patients met the clinical diagnostic criteria described by Bohan and Peter[1] (Table I). In 11 patients the diagnosis was clinically classified as definite, in 2 as probable, and in 3 as possible. There were no patients with idiopathic polymyositis (group I), 7 with dermatomyositis (group II), 5 with dermatomyositis-polymyositis associated with malignancy (group III), 2 with childhood dermatomyositis-polymyositis with vasculitis (group IV), and 2 with an overlap syndrome (group V). The adult patients ranged in age from 32 to 84 years (average 56); the 2 children were 2 and 10 years of age. Twelve of the patients were female and 4 male. One man had dermatomyositis; the other 3 men had dermatomyositis-polymyositis with malignancy (group III). The duration of disease ranged from 1 to 72 months (average 21). Twelve patients had been treated with corticosteroids; 1 (Case 6) had received both steroids and cyclophosphamide.

Clinical Manifestations

Cardiovascular: Of the 7 patients with dermatomyositis (group II), 3 patients (Cases 1, 6, and 7) had congestive heart failure. The electrocardiogram of Patient 1, a 53 year old woman, showed left bundle branch block; in the others, the electrocardiographic changes were nonspecific. Patient 6 had high output congestive failure. An echocardiogram in this patient demonstrated an ejection fraction of 64%, a hypokinetic septum and small left ventricular cavity, dilatation of the right ventricle, and a decreased EF slope of the mitral valve (28 mm/s), with the normal being greater than 70 mm/s. The poor left ventricular function was thought to be secondary to myocardial involvement with polymyositis. One patient in the dermatomyositis group had Raynaud's phenomenon. Of the 4 patients with malignancy-associated dermatomyositis (group III), 2 (Cases 8 and 10) had congestive heart failure. One patient (Case 9), a 68 year old man, had right bundle branch block. In the others, the electrocardiographic changes were nonspecific. Both patients with childhood dermatomyositis (Group IV) had congestive heart failure; 1 patient (Case 13) had a prolonged P-R interval. Raynaud's phenomenon was present in both patients with overlap syndromes (group V). Both of these patients demonstrated features of progressive systemic sclerosis as well as polymyositis. In 1 patient (Case 16), features of polyarteritis nodosa were also present.

The direct cause of death was cardiovascular in only 3 patients. In 1 patient (Case 7) death was due to acute congestive heart failure, in 1 (Case 8) it was due to an arrhythmia occurring in the setting of congestive failure, and in another (Case 3) it was secondary to a dissecting aneurysm involving the ascending aorta, with extension into the right and left coronary arteries. No patient had evidence of hemodynamically significant valve dysfunction.

Pulmonary: Two patients had significant pulmonary involvement. One patient (Case 6) presented with

symmetric additive polyarthritis involving the hands, knees, and feet. Over the next 2 months, an erythematous malar rash as well as a heliotrope rash developed, as did a positive Gottron's sign, proximal muscle weakness, and rapidly progressive respiratory insufficiency. Despite treatment with both steroids and cyclophosphamide, ventilatory function deteriorated. Pulmonary function tests performed 10 days before death revealed a forced vital capacity (FVC) of 1.72 liters (32.9% predicted), forced expiratory volume in 1 minute (FEV_1) of 1.62 liters (36.9% predicted), FEV_1/FVC 94.3% (84% predicted), total lung capacity 2.61 liters (35.4% predicted), vital capacity 1.80 liters (34.4% predicted), functional residual capacity 1.53 liters (36.9% predicted), and residual volume 0.81 liters (38.1% predicted). The carbon monoxide diffusing capacity (D_LCO) was 4.7 ml/m/mm Hg (25.2% of predicted). Arterial blood gases on room air showed PaO_2 47 mm Hg, $PaCO_2$ 28 mm Hg, and pH 7.42 (oxygen saturation 84.8%). In this patient high output cardiac failure developed. Despite vigorous diuresis and mechanical ventilation, the patient ultimately died. Another patient (Case 15) had an overlap syndrome with features of progressive systemic sclerosis and marked interstitial fibrosis. This patient had progressive pulmonary disability and respiratory arrest at home with unsuccessful resuscitation.

Pathologic Findings

Skeletal muscle: Skeletal muscle biopsy performed during life in all cases except Patients 11 and 12 showed histologic alterations consistent with polymyositis.

B = black; CHF = congestive heart failure; Def = definite; ECG = electrocardiogram; F = female; HBP = high blood pressure; LBBB = left bundle branch block; LVH = left ventricular hypertrophy; M = male; NS ST-T waves = nonspecific ST-T wave changes; MI = myocardial infarct; Poss = possible; Prob = probable; RBBB = right bundle branch block; tachy = tachycardia; W = white; WNL = within normal limits; + = present; − = absent.

Skeletal muscle alterations were present at autopsy in 13 patients (81%). The pathologic features included lymphocytic infiltration, necrosis of muscle fibers, and variability in fiber size and staining characteristics (Fig. 1). Focal fibrosis suggestive of resolved myositis was seen in several patients. Marked regenerative activity was seen in 1 (Case 8).

Cardiovascular (Table II): The adult heart weights ranged from 190 to 690 g (average 378). No anomalies were present in the tricuspid, pulmonic, and aortic valves in any patient. In 1 patient the mitral valve showed a mild floppy change suggestive of functional prolapse; this lesion had apparently not been hemodynamically significant. Four patients had calcific mitral anulus fibrosis. All of them were in the older age group and all were female (Cases 4, 8, 11, and 15). Coronary atherosclerosis was present in 7 patients and severe in 2 (Cases 8 and 16), moderate in 2 (Cases 3 and 12), and mild in 4 (Cases 1, 4, 7, and 9). Three patients (Cases 9, 10, and 15) had remote infarcts. In Patient 9 the remote infarct was clearly related to severe coronary atherosclerosis, and this patient subsequently underwent a coronary artery bypass procedure. Patient 15 had a remote infarct in the absence of coronary atherosclerosis. This patient had systemic Raynaud's phenomenon and presumably sustained myocardial damage on the basis of cardiac Raynaud's phenomenon.[19–21] Patient 16, who also had systemic Raynaud's phenomenon and histologic features of polyarteritis nodosa, had marked arteritis of the coronary arteries and multiple recent myocardial infarcts. Patient 10 had remote and recent myocardial infarcts in the absence of atherosclerosis. Five patients with coronary atherosclerosis had received steroids. In the 3 who had not received steroids, atherosclerosis was severe in 1 (Case 9), moderate in 1 (Case 12), and mild in 1 (Case 8).

The conducting system, studied histologically in 11 patients, was abnormal in 2 (18%). One patient (Case 1) had microscopic findings consistent with direct involvement by the disease process. There was lymphocytic infiltration and fibrosis of the sinoatrial node, and contraction band necrosis and lymphocytic infiltration of the left bundle branch, which correlated with the electrocardiographic finding of left bundle branch block. One other patient (Case 7) showed attenuation of the left bundle branch, without evidence of active myocarditis. Electrocardiograms in this patient were not available. The patient with the electrocardiographic finding of right bundle branch block (Case 9) had no microscopic alteration within the conduction system.

Histologic examination of the heart in the 3 patients with clinical evidence of Raynaud's phenomenon (Cases 4, 15, and 16) revealed the myocardial changes previously described.[19–21] There was focal fibrosis

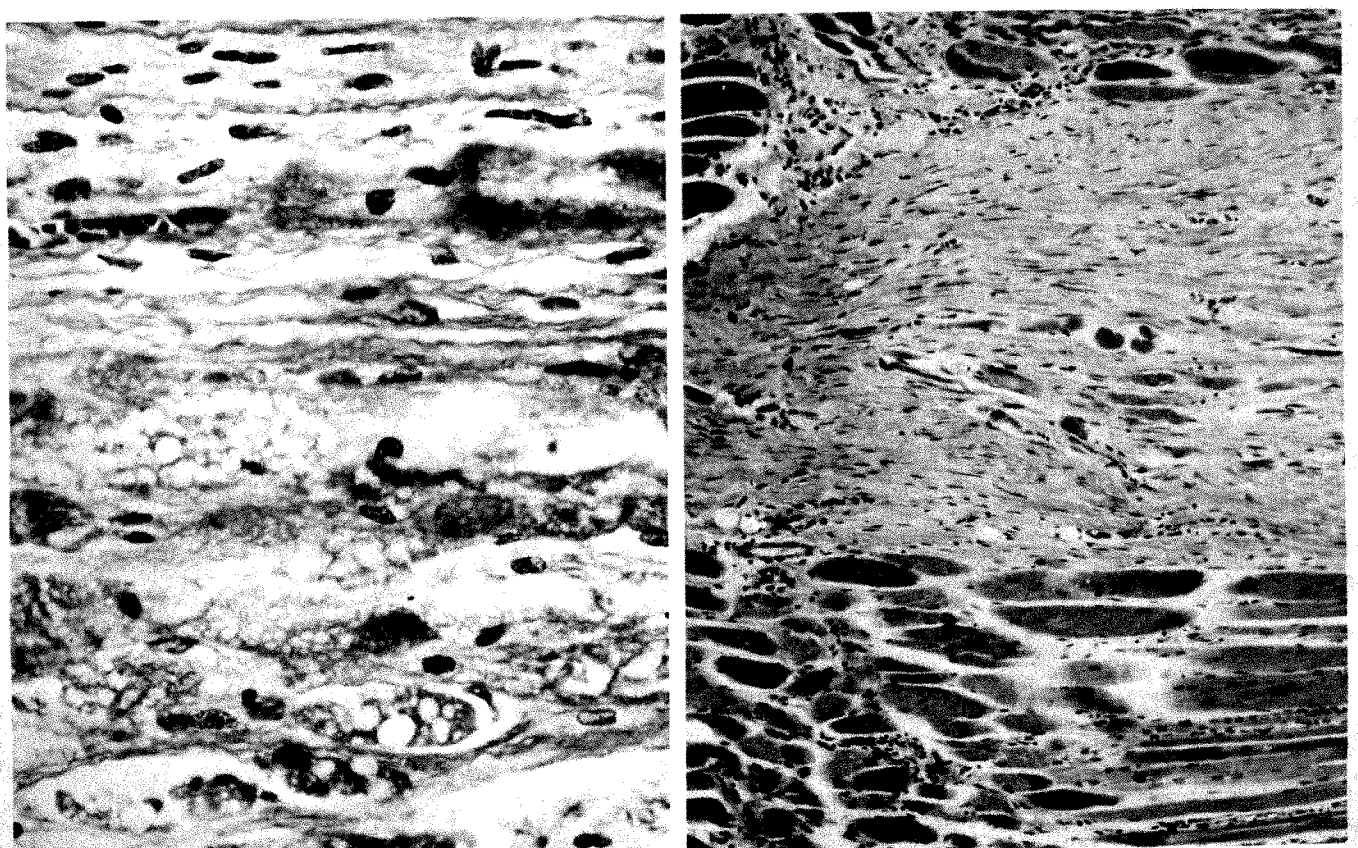

FIGURE 1. Skeletal muscle with focal replacement fibrosis (**left**) in an 84 year old woman (Case 8) and active degeneration of myocytes (**right**) in a 39 year old woman (Case 5). (Both stained with hematoxylin and eosin; **left**, magnification ×100; **right**, magnification ×500.)

TABLE II Pathologic Findings in 16 Patients With Polymyositis-Dermatomyositis

Patient	Heart			Skeletal Muscle	Lungs
	Gross	Conduction System	Myocardium		
	Group II. Dermatomyositis				
1	272 g; floppy mitral valve; focal fibrosis, left ventricle; mild coronary atherosclerosis	SAN: fibrosis, LI; AVN, His, RB: normal; LB: contraction band necrosis, LI	Interstitial myocarditis; degeneration of individual myocytes; focal fibrosis; medial sclerosis of vessels	Moderate variability in fiber size; LI; mild activity	Interstitial fibrosis and fibrosing alveolitis; edema; thromboemboli; CMV
2	400 g	*	. . .	Moderate LI, muscle destruction; mild activity	Interstitial pneumonitis; edema; fat & marrow emboli
3	430 g; moderate coronary atherosclerosis; dissecting aneurysm of aorta extending into coronary arteries	*	. . .	Mild perivascular LI	Moderate hemorrhage
4	275 g; mild CMAF; mild coronary atherosclerosis	SAN, AVN, His, RB, LB: normal	Focal fibrosis	LI, muscle degeneration; mild activity	Bronchopneumonia; edema
5	314 g	SAN, AVN, His, RB, LB: normal	. . .	LI, muscle degeneration; mild activity	Bronchopneumonia; hyaline membranes
6	460 g	SAN AVN, His, RB, LB: normal	. . .	LI; muscle destruction; marked activity	Interstitial pneumonitis & fibrosis; hyaline membranes
7	460 g; mild coronary atherosclerosis	SAN, AVN:* His, RB: normal; LB: mild attenuation	Mild chronic inflammatory infiltrate; mild contraction band necrosis	LI; mild activity	Mild hemorrhage & edema; focal granulomas
	Group III. Dermatomyositis With Malignancy				
8	190 g; moderate CMAF; mild coronary atherosclerosis	SAN, AVN, His, RB, LB: normal	Moderate to marked focal fibrosis; variability in muscle size	Marked LI; variation in muscle size; focal necrosis; myocyte regeneration; marked activity	Mild hemorrhage, edema, and organizing thromboemboli corpora amylacea
9	405; remote anteroseptal infarct; marked coronary atherosclerosis; coronary artery bypass grafts	SAN, AVN, His, RB, LB: normal	. . .	. . .	Small cell carcinoma; thromboemboli; infarct; edema
10	420 g	SAN, AVN, His, RB, LB: normal	Remote & recent infarcts, left ventricle	Marked inflammatory infiltrate & myocyte degeneration; marked activity	Metastatic transitional cell carcinoma; bronchopneumonia; emphysema; fibrosis; hemorrhage
11	260 g; CMAF	SAN, AVN, His, RB, LB: normal	. . .	. . .	Small cell carcinoma; hemorrhage; infarct; edema
12	330 g; moderate coronary atherosclerosis	SAN, AVN, His, RB, LB: normal	. . .	. . .	Emphysema; mild fibrosis; hemorrhage
	Group IV. Childhood Dermatomyositis With Vasculitis				
13	170 g	*	Mild interstitial inflammatory infiltrate	Moderate LI; active vasculitis, vascular intimal proliferation	Marked edema & purulent pleuritis; mild hemorrhage
14	60 g; probe patent foramen ovale	*	. . .	Marked LI with myocyte destruction; marked vasculitis	Marked purulent pleuritis, moderate hemorrhage & edema
	Group V. Mixed Overlap Syndromes				
15	390 g; CMAF; remote infarct, right ventricle; focal fibrosis	*	Marked proliferation, intima, coronary arteries; moderate focal fibrosis	Moderate LI; focal loss of myocytes; medial sclerosis, vessels, active	Interstitial fibrosis & pneumonitis; bronchopneumonia; edema
16	690 g; massive right atrial thrombus; marked coronary atherosclerosis	SAN, AVN, His, RB, LB: normal	Marked polyarteritis; multiple infarcts	LI & muscle destruction; marked activity	Interstitial pneumonitis; edema; hemorrhage; bronchopneumonia

* Missing data.
AVN = atrioventricular node; CMAF = calcific mitral anulus fibrosis; His = His bundle; LB = left bundle; LI = lymphocytic infiltrate; RB = right bundle; SAN = sinoatrial node.

without inflammation in 1 and marked intimal proliferation of the coronary arteries and focal fibrosis in another. The 3 patients, who also had features of polyarteritis nodosa, had marked arteritis of the coronary arteries and multiple infarcts.

Microscopic examination of the heart showed pathologic alterations attributable to involvement with a polymyositis-dermatomyositis disease process in 4 patients (25%) (Cases 1, 7, 8, and 13). These findings consisted of an interstitial inflammatory cell infiltrate, contraction band necrosis, degeneration of individual myocytes, variation in myocyte size, and focal fibrosis (Fig. 2).

All 4 patients with active myocarditis had congestive heart failure. However, congestive failure was present in a total of 7 patients (44%), 1 of whom (Case 6) had high output failure. Thus, in 25% of cases, congestive heart failure was directly attributable to myocarditis related to the underlying disease. Of the 4 patients with congestive failure secondary to polymyositis, 3 had abnormal electrocardiograms. In the other, the electrocardiographic data were unobtainable. One patient (Case 1) had left bundle branch block owing to histologically documented involvement of the left bundle (Fig. 3). Another patient (Case 8) showed sinus tachycardia and a remote posterior myocardial infarct on electrocardiography, which was not substantiated on pathologic examination. The 3rd patient (Case 13) had a prolonged P-R interval. In the other patients without histologic myocardial involvement by polymyositis-dermatomyositis the electrocardiographic findings were nonspecific (Table I).

Active myocarditis was always seen in the presence of active skeletal muscle myositis and was of comparable severity. However, 9 patients (Cases 2 to 6, 10, and 14 to 16) had skeletal muscle alterations without cardiac muscle involvement.

Focal fibrosis was present in a patchy distribution throughout the myocardium in 4 patients (25%). Two of these (Cases 14 and 15) had systemic Raynaud's phenomenon. Focal myocardial fibrosis may have arisen from coronary spasm.[19-21] In the other patients (Cases 1 and 8) coronary atherosclerosis was mild and the focal fibrosis was attributed to previous episodes of myocarditis.

Vascular changes were seen in both myocardial and skeletal muscle sections in 5 patients (31%) (*Fig. 4*). One patient (Case 1) had marked medial sclerosis of the coronary arteries associated with active myocarditis and focal fibrosis, suggesting remote injury. Both patients with childhood dermatomyositis had vascular changes. One patient (Case 13) showed active vasculitis with intimal proliferation. The other patient (Case 14) had marked active vasculitis. Both patients with overlap syndromes had vascular alterations. One patient with features of progressive systemic sclerosis (Case 13) had

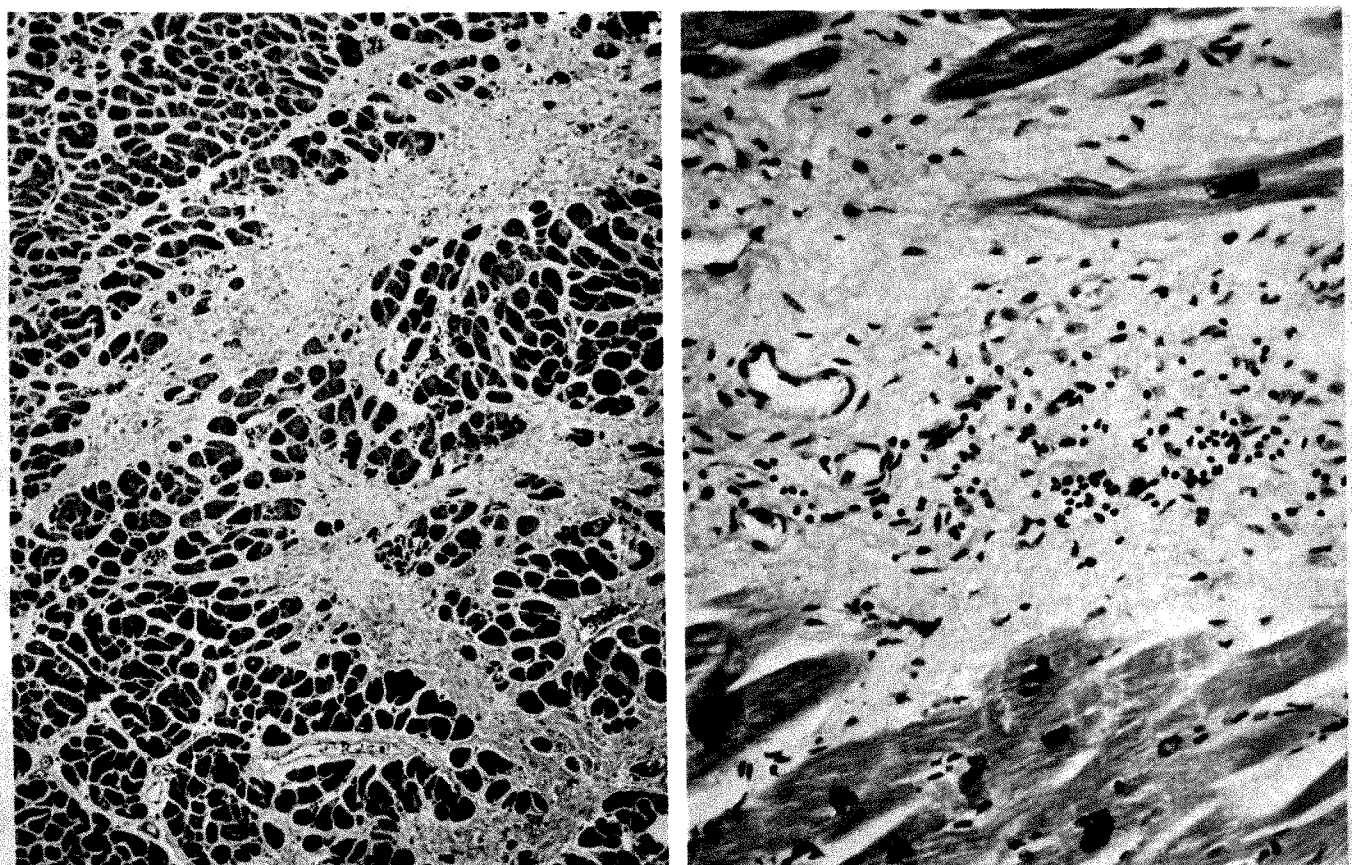

FIGURE 2. Cardiac muscle with focal replacement fibrosis (**left**) in a 64 year old woman (Case 4) and an interstitial inflammatory infiltration (**right**) in a 53 year old woman (Case 1). (Both stained with hematoxylin and eosin; **left**, magnification ×100; **right**, magnification ×500.)

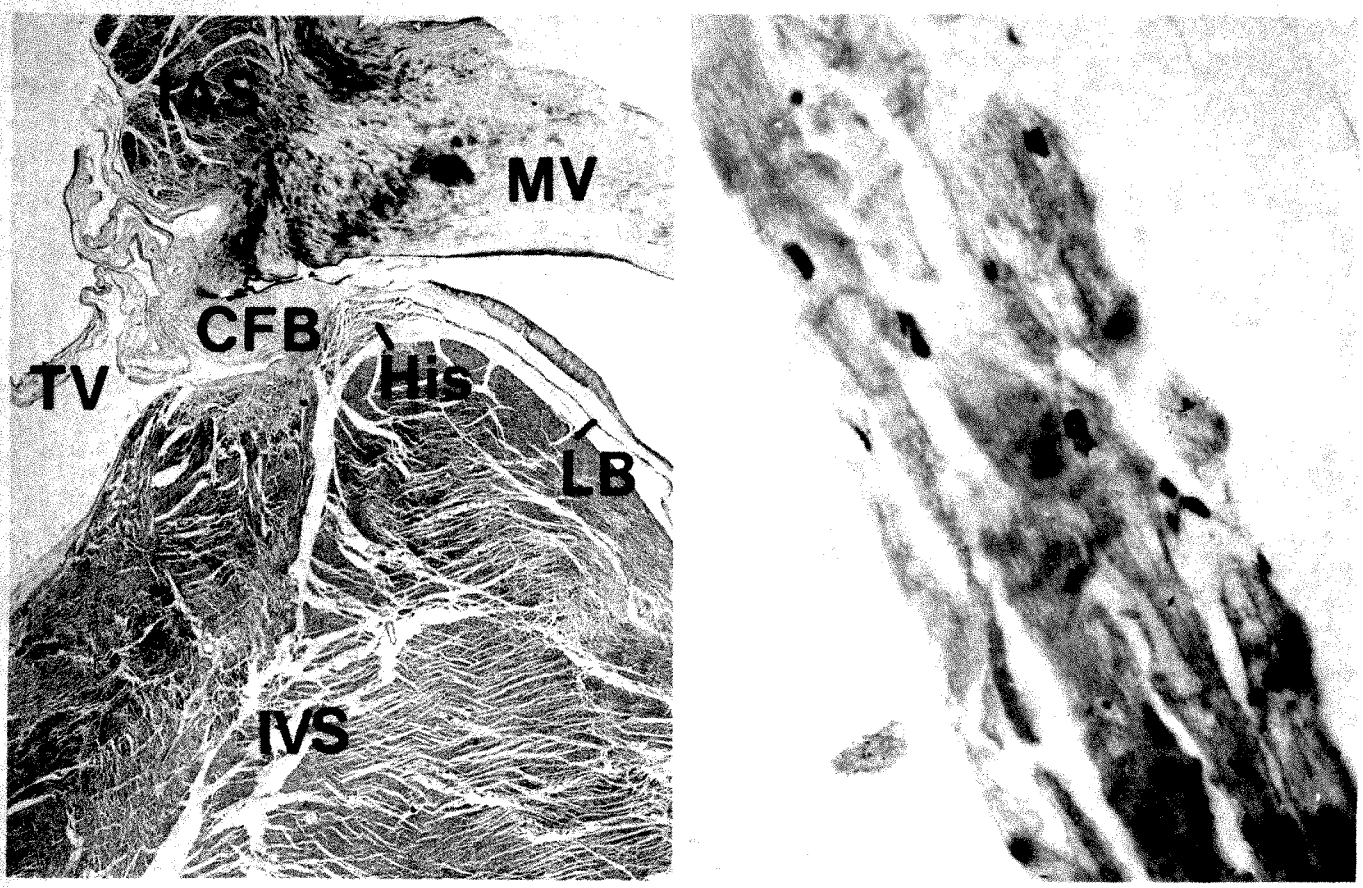

FIGURE 3. Case 1. Cardiac conduction system in a 53 year old woman with left bundle branch block. **Left,** the left bundle (LB) and distal portion of the His bundle (His). The interatrial septum (IAS) is at the **top** and the interventricular septum (IVS) **below**. The mitral (MV) and tricuspid (TV) valves are attached to the central fibrous body (CFB). **Right,** contraction band necrosis of the left bundle. The myocytes of the bundle show irregular coarse transverse condensations of sarcoplasm and their nuclei are pyknotic. (**Left,** Verhoeff-van Gieson elastin stain, magnification ×9; **right,** hematoxylin and eosin stain, magnification ×490.)

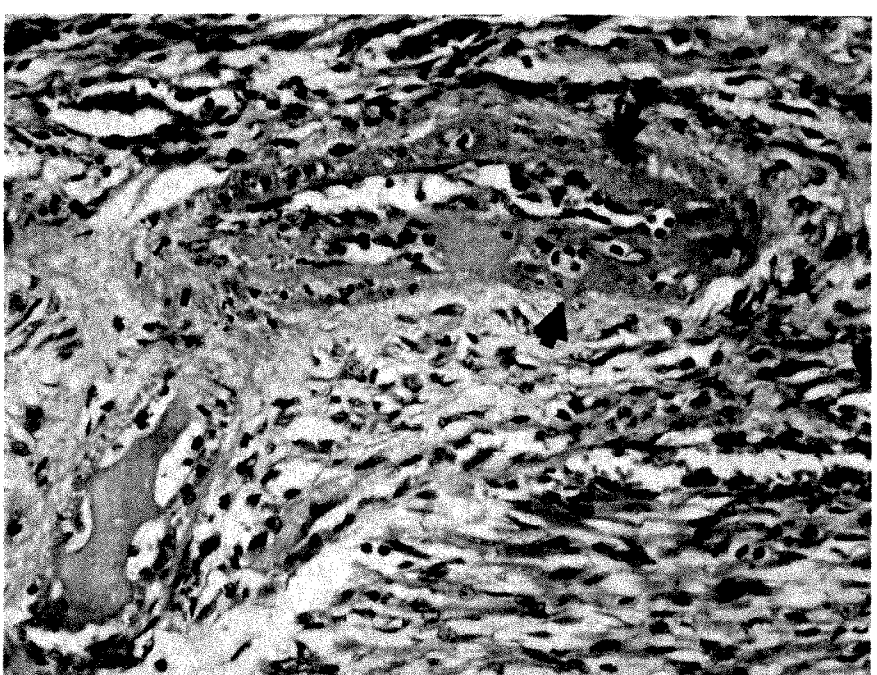

FIGURE 4. Case 14. Small artery in the skeletal muscle of a 2 year old girl with childhood dermatomyositis. There is necrosis of the portion of arterial wall between the **arrows.** (Hematoxylin and eosin stain; magnification ×250.)

typical intimal proliferation of the coronary arteries in association with focal fibrosis[19–21]; this patient had marked medial sclerosis of the skeletal muscle arteries. The other (Case 16) had marked arteritis of the coronary arteries as well as those of the gastrointestinal tract; she also had polyarteritis nodosa.

Pulmonary: Five patients had pulmonary pathologic findings typical of those described in polymyositis.[8,22–24] Two patients demonstrated marked interstitial fibrosis. In 1 (Case 6) it was associated with marked active interstitial pneumonitis and intimal proliferation within the pulmonary vessels. This patient's clinical course was dominated by respiratory failure. The other patient with marked interstitial fibrosis (Case 15) also had moderate interstitial pneumonitis. This patient fell into the overlap group with features of progressive systemic sclerosis. Patient 1 had mild interstitial fibrosis and cytomegalovirus inclusions within the lung. Patient 16, who had a syndrome with features of polymyositis, progressive systemic sclerosis, and polyarteritis nodosa, had marked interstitial pneumonitis and hyaline membranes. Patient 2 had mild interstitial pneumonitis.

Other organ systems: Six patients had gastrointestinal pathologic changes. Four (Cases 1, 6, 15, and 16) demonstrated fibrosis of the muscularis. Two (Cases 13 and 16) had vasculitis of the gastrointestinal vessels; Patient 13 had childhood dermatomyositis in which esophageal perforation with sepsis was the cause of death; Patient 16 had features of polyarteritis nodosa in other organs. One patient (Case 3) had a lymphocytic infiltrate in the muscularis of the esophagus.

Although 13 patients had clinical evidence of skin involvement, it was histologically documented at autopsy in only 4 (Cases 1, 6, 8, and 13). This discrepancy is perhaps due to the occasionally transient nature of the skin manifestations as well as to autopsy limitations that precluded sampling of the face and limbs.

Discussion

Since the classic description of Oppenheim[25] in 1899, it is recognized that polymyositis may involve the heart. Most previous reports have acknowledged that cardiac involvement occurs in polymyositis but that it is uncommon.[1–10,12–16] This study of 16 autopsied patients with polymyositis syndromes demonstrated pathologic evidence of active myocarditis in 4 (25%) and focal fibrosis in 4 (25%). These findings suggest that cardiac involvement in polymyositis and dermatomyositis is not uncommon.

Electrocardiographic and conduction system abnormalities: Previous reports have suggested that several electrocardiographic abnormalities may indicate myocardial involvement in polymyositis, including atrial and ventricular arrhythmias,[1,3,5–7,11,17] nonspecific ST-T wave changes,[3,4,6,7,11] and left axis deviation.[6] Several studies describe conduction abnormalities in the setting of polymyositis.[1,3,5–7,11–15,17] There are 3 studies with pathologic documentation of conduction system lesions.[12,13,15] Lynch[12] studied a patient with complete heart block in whom examination of the conduction system revealed extensive fibrosis. Schaumberg et al.[13] described a 26 year old patient with 2:1 atrioventricular block, with fibrous replacement of the distal 3rd of the bundle of His, the atrioventricular node, and the sinoatrial node. Lightfoot et al.[15] observed a patient with intermittent complete heart block, with marked fibrosis of both bundle branches. However, this patient also had considerable coronary atherosclerosis and narrowing of the right coronary artery. The 2 largest series, those of Denbow et al.[11] and Gottdiener et al.,[17] do not address the histologic correlation of electrocardiographic abnormalities. Our study showed pathologic alterations in 2 of the 11 conduction systems studied, but in only 1 was involvement directly attributable to polymyositis.

Congestive heart failure: Congestive heart failure has been observed in patients with polymyositis.[3,7,9,11,12] In a large clinical review of 153 patients, Bohan et al.[3] recorded a frequency of 3.3%. Nine of the 20 patients studied at autopsy by Denbow et al.[11] had previous evidence of congestive heart failure. However, these workers histologically demonstrated active myocarditis, replacement fibrosis, and small vessel disease in only 6 patients (4 with congestive heart failure and 2 without). They suggested that patients with polymyositis may have cardiomyopathy that is not apparent by light microscopy and cautioned that histologic documentation of myocardial replacement fibrosis and small vessel disease did not necessarily imply that the patient had hemodynamically significant cardiomyopathy. Congestive heart failure was present in 44% of our patients, including all 4 patients with active myocarditis. Further studies, particularly at the electron microscopic level, are needed to assess myocardial changes contributing to congestive heart failure in polymyositis. Quantitation of creatine kinase MB isoenzyme bands at peak periods of myocardial failure in these patients would also be of interest.

Coronary atherosclerosis: The coronary atherosclerosis observed in these patients may be related in part to previous steroid therapy,[26] although atherosclerosis was present in 3 patients who had not received corticosteroids. Two of these patients were in their 60s; 1 was 84 years of age. Of the 5 patients with atherosclerosis who received steroids, 1 was 32, 2 were 49, 1 was 53, and 1 was 64 years of age. The relation of dermatomyositis-polymyositis to the development of coronary atherosclerosis is unclear.

Mitral valve prolapse: This anomaly was described in patients with polymyositis by Gottdiener et al.,[17] who demonstrated echocardiographic evidence of this in 65% of 17 patients, 7 of whom had a midsystolic click. None of our patients had pathologic alterations of the mitral valve unequivocally indicative of functional prolapse. One patient (Case 7) who died in pulmonary edema did show floppy change of the mitral valve, a condition associated with prolapse.[27] This patient also had histologic evidence of myocarditis.

Hyperkinetic cardiac failure: A hyperkinetic cardiovascular state has been observed in polymyositis.[16,17] Babka and Pepine[16] studied a 40 year old man with polymyositis with hyperkinetic congestive failure documented by cardiac catheterization with left ven-

triculography. His cardiac failure was refractory to digitalis and diuretics but responded to treatment with propranolol. Autopsy revealed no histologic abnormalities of the myocardium or coronary arteries. Gottdiener et al.[17] demonstrated significantly greater cardiac performance by echocardiographic documentation of enhanced ejection phase indexes of left ventricular function in patients with polymyositis as compared with matched control patients. One patient in our study had high output congestive failure with hyperkinesia documented by echocardiography; at autopsy this heart was histologically normal.

In summary, our study demonstrated pathologic evidence of cardiac involvement in a total of 7 of 16 patients (44%). Evidence of myocardial involvement included active myocarditis, focal fibrosis, vasculitis, intimal proliferation, and medial sclerosis of vessels. Conduction system changes were present in 2 (18%) of 11 patients studied.

Implications: The correlation of myocardial damage with skeletal muscle involvement cannot be fully resolved by our study. Myocardial involvement was always seen in the presence of active skeletal muscle myositis; however, the reverse was not always true. With an appreciation of the frequency of cardiac involvement in polymyositis, future noninvasive studies may help to further delineate the association of myocarditis with myositis.

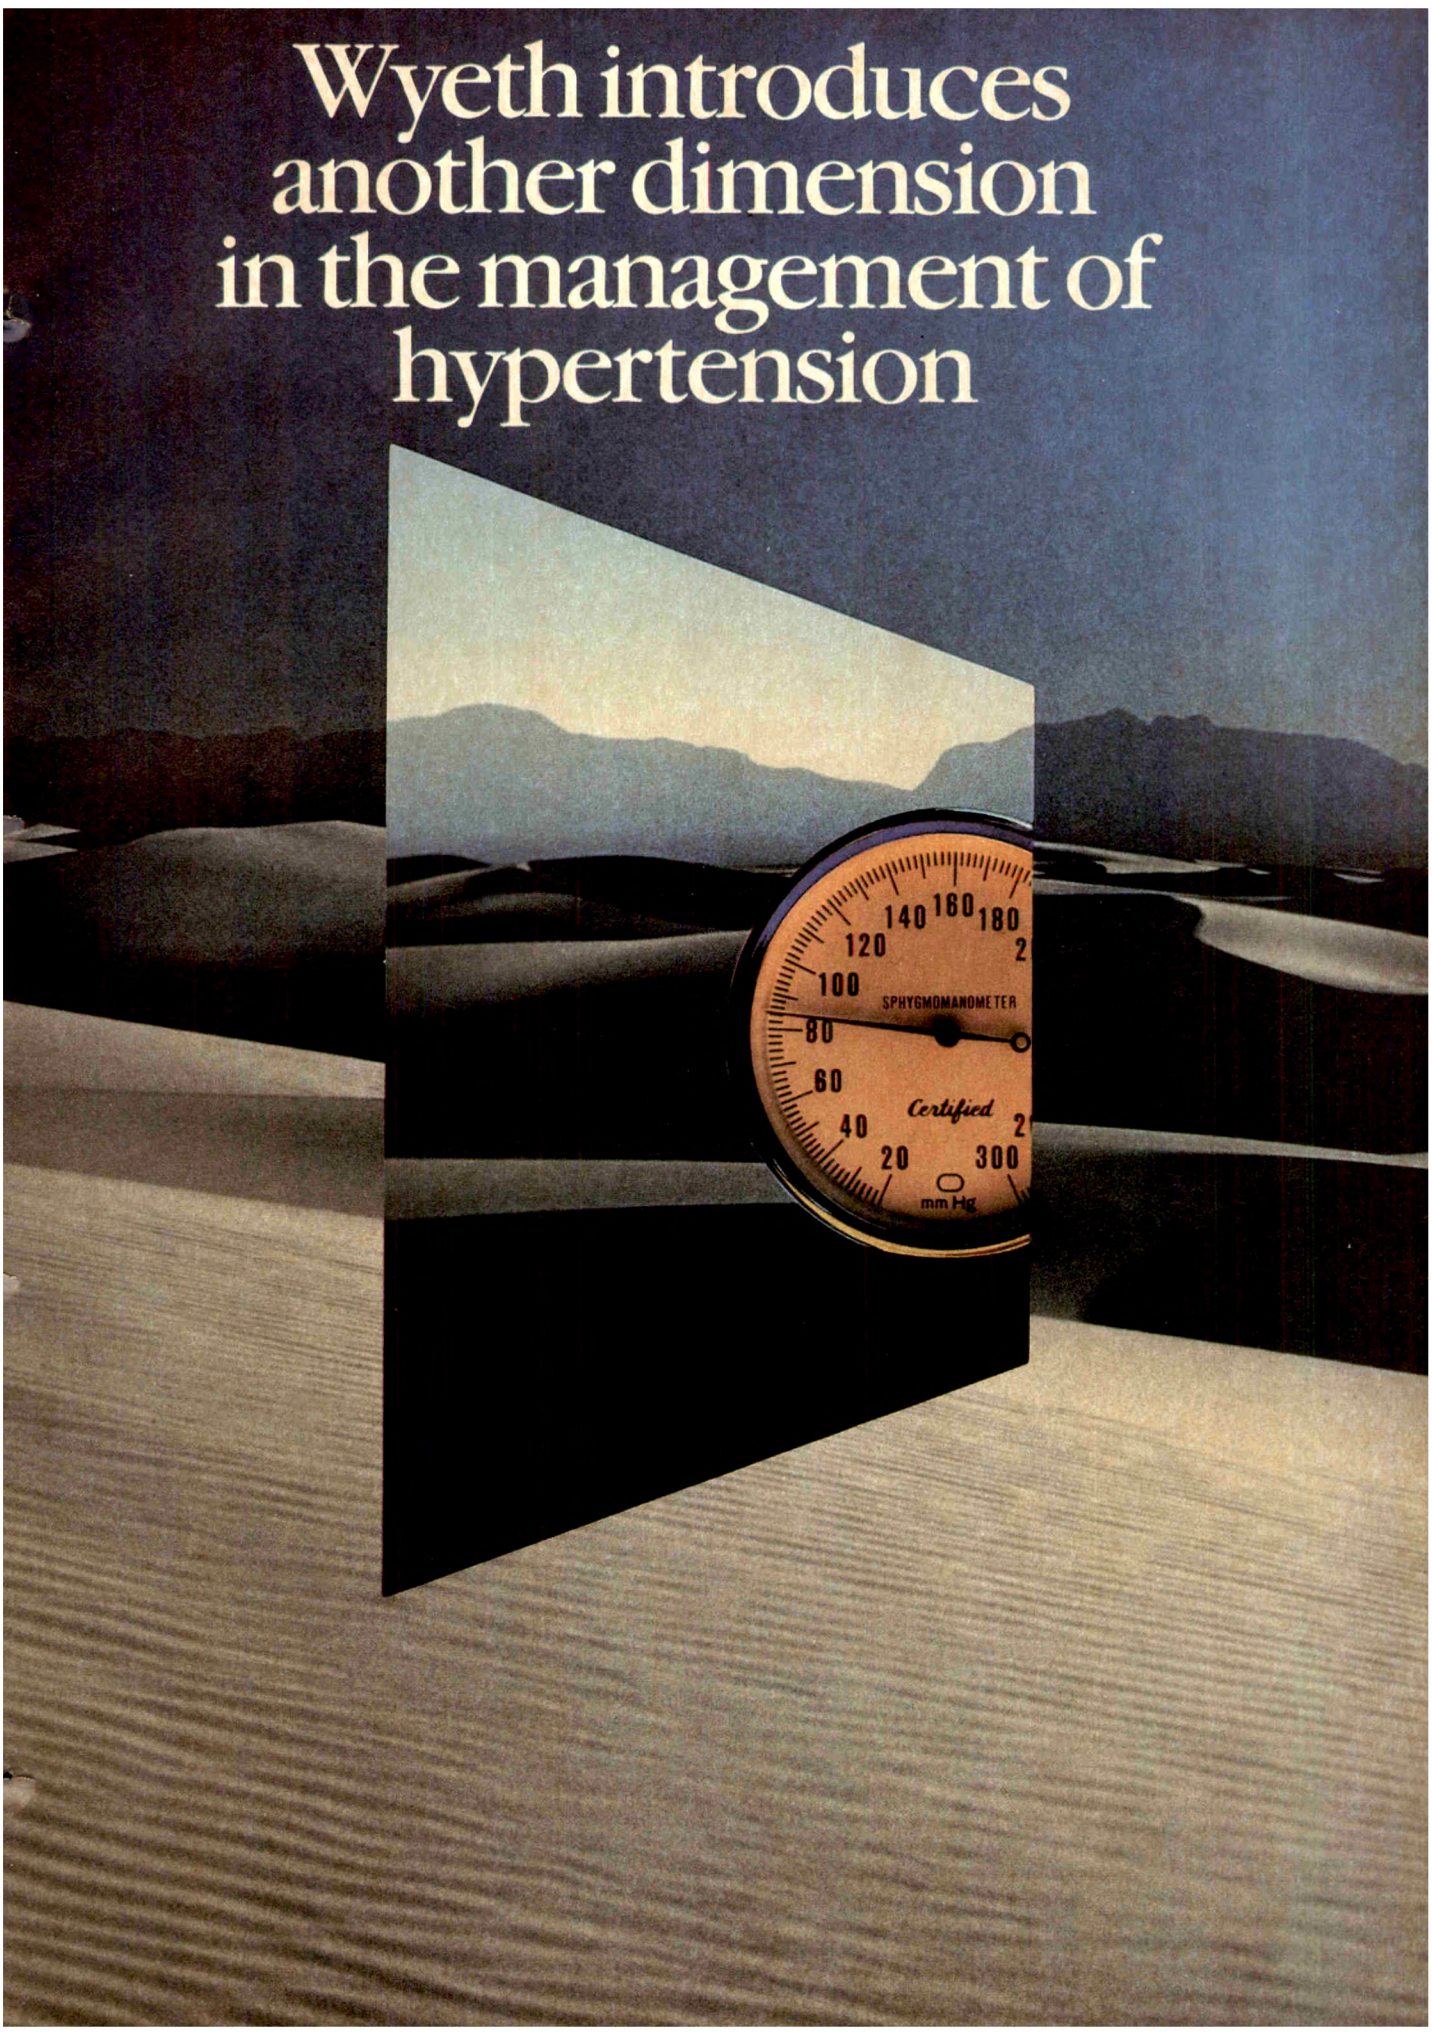
Wyeth introduces another dimension in the management of hypertension



In clinical trials to date:

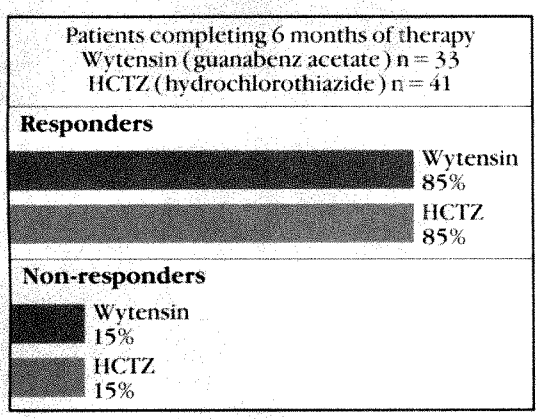
no potassium depletion
no volume depletion
no hyperlipidemia
no hyperuricemia
no hypercalcemia

no acid-base disturbances
no increased renin activity
no increased catecholamines
no azotemia
no hyperglycemia

Wyeth

Another dimension of management beyond the scope of diuretics

Highly effective in double-blind, multicenter studies



Important homeostatic advantages

	Wytensin	HCTZ
potassium	—	↓
renin	—	↑
glucose	—	↑
serum cholesterol	↓	↑
chloride	—	↓
uric acid	—	↑
calcium	—	↑
BUN	—	↑

Wytensin® did not induce long-term cardiovascular risk factors.[1]
Unlike diuretics, Wytensin can be used over the long-term without inducing atherogenic potential risk factors such as hyperlipidemia and hyperglycemia or arrhythmic risk factors such as hypokalemia. With Wytensin therapy a small decrease in heart rate and weight has been observed.

Wytensin® side effects are usually mild and transient.
Although dry mouth and/or drowsiness were the most frequently noted side effects, these subjective complaints usually diminished or disappeared over time. Only 9% of patients discontinued therapy due to drowsiness or dry mouth.
About one third of patients who started Wytensin therapy with 8 mg twice daily experienced these side effects, but starting with 4 mg b.i.d.—the recommended starting dose—reduced both the incidence of these side effects and the consequent dropout rate. In all studies to date, discontinuance of therapy for all side effects occurred in about 15% of patients.

Wytensin® may lower the price the patient pays for therapy.
Because Wytensin did not induce electrolyte and metabolic imbalance, it may save patients trouble and money. A Wytensin prescription reduces the need for frequent laboratory testing as well as for K-sparing agents or K supplements and other agents that frequently cost more than diuretics alone.

New

WyTensin®

(guanabenz acetate)

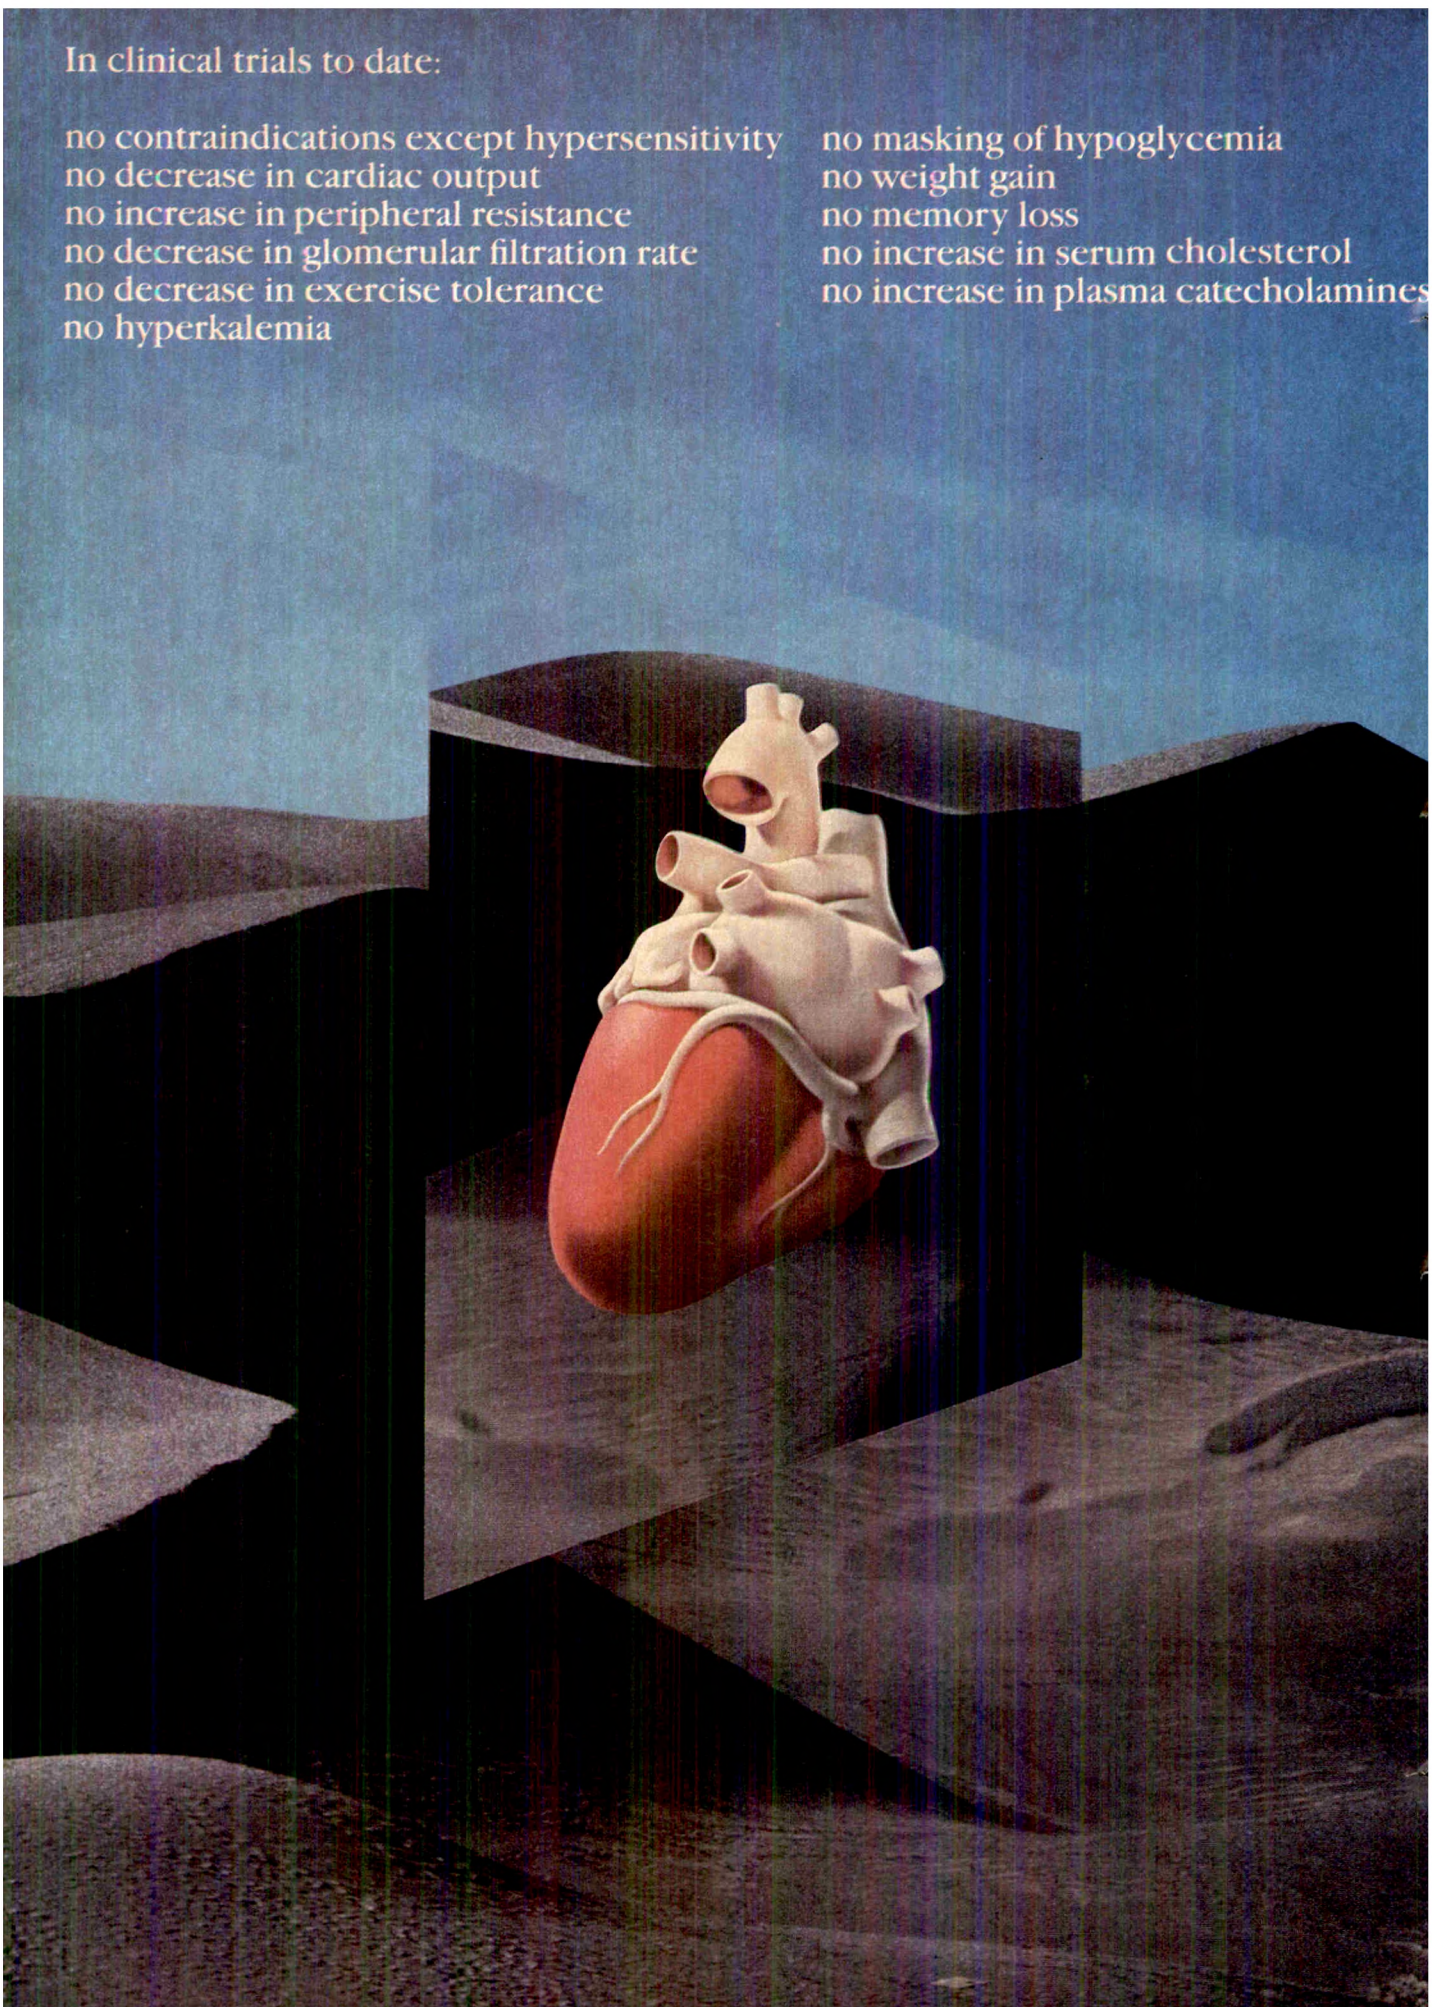
4 mg b.i.d.

Initial monotherapy in hypertension

See important information on last page.

In clinical trials to date:

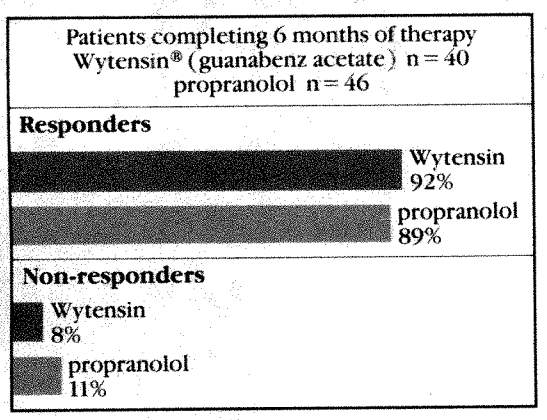
no contraindications except hypersensitivity
no decrease in cardiac output
no increase in peripheral resistance
no decrease in glomerular filtration rate
no decrease in exercise tolerance
no hyperkalemia
no masking of hypoglycemia
no weight gain
no memory loss
no increase in serum cholesterol
no increase in plasma catecholamines



Wyeth

Another dimension of management beyond the scope of beta-blockers

Highly effective in double-blind, multicenter studies



Important homeostatic advantages

	Wytensin	propranolol
potassium	—	↑
serum cholesterol	↓	—
cardiac output	—	↓
glomerular filtration rate	—	↓
peripheral resistance	↓	↑
exercise tolerance	—	↓
plasma catecholamines	↓	↑

Wytensin® lacks the risks of beta-blockade.
Wytensin® is less problematic than beta-blockers, which are contraindicated in many patients and must be used with caution in many others. For instance, exercise intolerance, nightmares, and memory failure can be problems with beta-blockers, and in many black and/or elderly patients, beta-blockade is ineffective.

Wytensin® side effects are usually mild and transient.
The subjective complaints of drowsiness and dry mouth were the most frequently noted side effects and usually diminished or disappeared over time. During initial therapy, patients should be cautioned against driving automobiles or operating dangerous machinery.

Wytensin® can be used in a broader spectrum of hypertensives.
In contrast to beta-blockers, Wytensin has no contraindications except hypersensitivity and is effective regardless of the aging process or racial factors. And, unlike beta-blockers, Wytensin causes a slight decrease in serum cholesterol and maintains potassium balance. Moreover, Wytensin does not cause clinically significant bradycardia or decreased cardiac output. There is no stimulation of vasopressor mechanisms.[2]

New

WyTensin®

(guanabenz acetate)

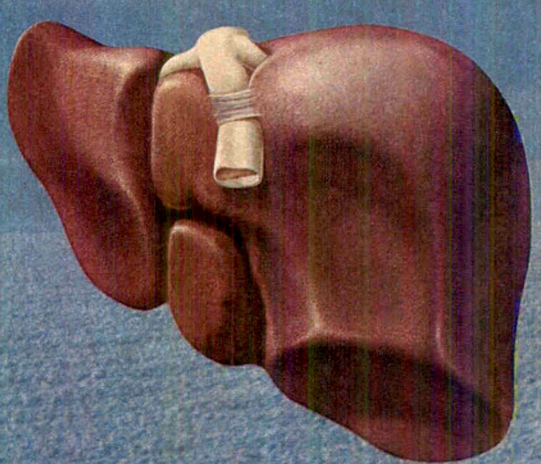
4 mg b.i.d.

Initial monotherapy in hypertension

See important information on last page.

In clinical trials to date:

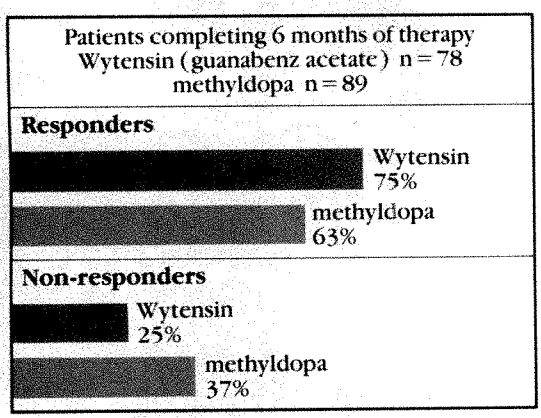
no sodium retention
no weight gain
no decrease in GFR
no immunological disturbances
no liver damage
no hemolytic anemia



Wyeth

Another dimension of management beyond the scope of methyldopa

Highly effective in double-blind, multicenter studies



Important homeostatic advantages

	Wytensin	methyldopa
sodium excretion	–	↓
plasma volume	–	↑
weight	↓	↑
glomerular filtration rate	–	↓

Wytensin® does not produce sodium retention or volume expansion.[3]
Methyldopa causes sodium retention and volume expansion with consequent development of drug tolerance. In contrast, drug tolerance has not developed with Wytensin probably because it does not induce retention of sodium and body fluid.

Wytensin® is virtually free of serious adverse reactions.
Unlike methyldopa, Wytensin does not produce immunological blood or liver toxicity or produce a positive Coombs' test. Wytensin also lacks the relatively high incidence of sexual dysfunction or mental depression seen with methyldopa.

Wytensin® side effects are often transient or avoidable.
Patients may experience drowsiness and dry mouth early during Wytensin therapy, but these effects are mostly mild, especially when the initial dosage is 4 mg b.i.d., with the second dose administered **h.s.**

New

WyTensin®

(guanabenz acetate)

4 mg b.i.d.

Initial monotherapy in hypertension

See important information on last page.

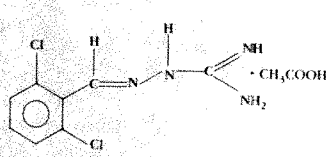
Initial monotherapy in hypertension

New Wytensin® (guanabenz acetate) 4 mg b.i.d.

More than 1,400 patients evaluated
No sodium retention
No electrolyte or metabolic risk factors
A favorable therapeutic index
Convenient, compliance-enhancing b.i.d. dosage
No contraindications except hypersensitivity

Description

Wytensin (guanabenz acetate), an antihypertensive agent for oral administration, is an aminoguanidine derivative, 2,6-dichlorobenzylideneaminoguanidine acetate, and its structural formula is:



It is an odorless, white to off-white, crystalline substance, sparingly soluble in water and soluble in alcohol, with a molecular weight of 291.14. Each tablet of Wytensin is equivalent to 4 mg or 8 mg of free guanabenz base.

Wytensin is available as 4 or 8 mg tablets for oral administration.

Clinical Pharmacology

Wytensin is an orally active central alpha-2 adrenergic agonist. Its antihypertensive action appears to be mediated via stimulation of central alpha adrenergic receptors, resulting in a decrease of sympathetic outflow from the brain at the bulbar level to the peripheral circulatory system.

PHARMACOKINETICS
In human studies, about 75% of an orally administered dose of Wytensin is absorbed and metabolized with less than 1% of unchanged drug recovered from the urine. Peak plasma concentrations of unchanged drug occur between two and five hours after a single oral dose. The average half-life for Wytensin is about 6 hours. The site or sites of metabolism of Wytensin and the consequences of renal or hepatic insufficiency on excretion of Wytensin or its metabolites have not been determined. The effect of meals on the absorption of Wytensin has not been studied.

PHARMACODYNAMICS
The onset of the antihypertensive action of Wytensin begins within 60 minutes after a single oral dose and reaches a peak effect within two to four hours. The effect of an acute single dose is reduced appreciably six to eight hours after administration, and blood pressure approaches baseline values within 12 hours of administration.

The acute antihypertensive effect of Wytensin occurs without major changes in peripheral resistance, but its chronic effect appears to be a decrease in peripheral resistance. A decrease in blood pressure is seen in both the supine and standing positions without alterations of normal postural mechanisms, so that postural hypotension has not been observed. Wytensin decreases pulse rate by about 5 beats per minute. Cardiac output and left ventricular ejection fraction are unchanged during long-term therapy.

With effective control of blood pressure in hypertensive patients, Wytensin has not demonstrated any significant effect on glomerular filtration rate, renal blood flow, renal sodium or potassium excretion, renal concentrating ability, body fluid volume, or body weight. In clinical trials of six to thirty months, hypertensive patients whose blood pressure was controlled with Wytensin lost one to four pounds of body weight. The mechanism of this weight loss has not been established. Tolerance to the antihypertensive effect of Wytensin has not been observed.

During long-term administration of Wytensin, there is a small decrease in serum cholesterol and total triglycerides without any change in the high-density lipoprotein fraction. Plasma norepinephrine, serum dopamine beta-hydroxylase, and plasma renin activity are decreased during chronic administration of Wytensin. No changes in serum electrolytes, uric acid, blood-urea nitrogen, calcium, or glucose have been observed.

Wytensin and hydrochlorothiazide have been shown to have at least partially additive effects in patients not responding adequately to either drug alone.

Indications and Usage
Wytensin is indicated in the treatment of hypertension. It may be employed alone or in combination with a thiazide diuretic.

Contraindication
Wytensin is contraindicated in patients with a known sensitivity to the drug.

Precautions
1. Sedation: Wytensin causes sedation or drowsiness in a large fraction of patients. When Wytensin is used with centrally active depressants, such as phenothiazines, barbiturates, and benzodiazepines, the potential for additive sedative effects should be considered.

2. Patients with vascular insufficiency: Wytensin, like other antihypertensive agents, should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or severe hepatic or renal failure.

3. Rebound: Sudden cessation of therapy with central alpha agonists like Wytensin may rarely result in "overshoot" hypertension and more commonly produces an increase in serum catecholamines and subjective symptomatology.

INFORMATION FOR PATIENTS
Patients who receive Wytensin should be advised to exercise caution when operating dangerous machinery or driving motor vehicles until it is determined that they do not become drowsy or dizzy from the medication. Patients should be warned that their tolerance for alcohol and other CNS depressants may be diminished. Patients should be advised not to discontinue therapy abruptly.

LABORATORY TESTS
In clinical trials, no clinically significant laboratory test abnormalities were identified during either acute or chronic therapy with Wytensin. Tests carried out included CBC, urinalysis, electrolytes, SGOT, bilirubin, alkaline phosphatase, uric acid, BUN, creatinine, glucose, calcium, phosphorus, total protein, and Coombs' test. During long-term administration of Wytensin, there was a small decrease in serum cholesterol and total triglycerides without any change in the high-density lipoprotein fraction. In rare instances an occasional non-progressive increase in liver enzymes has been observed. However, no clinical evidence of hepatic disease has been found.

DRUG INTERACTIONS
Wytensin has not been demonstrated to cause any drug interactions when administered with other drugs, such as digitalis, diuretics, analgesics, anxiolytics, and antiinflammatory or antiinfective agents, in clinical trials. However, the potential for increased sedation when Wytensin is administered concomitantly with CNS depressant drugs should be noted.

DRUG/LABORATORY TEST INTERACTIONS
No laboratory test abnormalities were identified with the use of Wytensin.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY
No evidence of carcinogenic potential emerged in rats during a two-year oral study with Wytensin at doses up to 9.5 mg/kg/day, i.e., about 10 times the maximum recommended human dose. In the Salmonella microsome mutagenicity (Ames) test system, Wytensin at 200-500 mcg per plate or at 30-50 mcg/ml in suspension gave dose-related increases in the number of mutants in one (TA 1537) of five *Salmonella typhimurium* strains with or without inclusion of rat liver microsomes. No mutagenic activity was seen at doses up to those which inhibit growth in the eukaryotic microorganism, *Schizosaccharomyces pombe*, or in Chinese hamster ovary cells at doses up to those which were lethal to the cells in culture. In another eukaryotic system, *Saccharomyces cerevisiae*, Wytensin produced no activity in an assay measuring induction of repairable DNA damage. Reproductive studies showed a decreased pregnancy rate in rats administered high oral doses (9.6 mg/kg) of Wytensin, suggesting an impairment of fertility. The fertility of treated males (9.6 mg/kg) may also have been affected, as suggested by the decreased pregnancy rate of their mates, even though the females received Wytensin only during the last third of pregnancy.

PREGNANCY
Pregnancy Category C
WYTENSIN MAY HAVE ADVERSE EFFECTS ON THE FETUS WHEN ADMINISTERED TO PREGNANT WOMEN. A teratology study in mice has indicated a possible increase in skeletal abnormalities when Wytensin is given orally at doses of 3 to 6 times the maximum recommended human dose of 1.0 mg/kg. These abnormalities, principally costal and vertebral, were not noted in similar studies in rats and rabbits. However, increased fetal loss has been observed after oral Wytensin administration to pregnant rats (14 mg/kg) and rabbits (20 mg/kg). Reproductive studies of Wytensin in rats have shown slightly decreased live-birth indices, decreased fetal survival rate, and decreased pup body weight at oral doses of 6.4 and 9.6 mg/kg. There are no adequate, well-controlled studies in pregnant women. Wytensin should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS
Because no information is available on the excretion of Wytensin in human milk, it should not be administered to nursing mothers.

PEDIATRIC USE
The safety and effectiveness of Wytensin in children less than 12 years of age have not been demonstrated. Therefore, its use in this age group cannot be recommended at this time.

Adverse Reactions
The incidence of adverse effects has been ascertained from controlled clinical studies conducted in the United States and is based on data from 859 patients who received Wytensin for up to 3 years. There is some evidence that the side effects are dose-related.

The following table shows the incidence of adverse effects occurring in at least 5% of patients in a study comparing Wytensin to placebo, at a starting dose of 8 mg b.i.d.

Adverse Effect	Placebo (%) n = 102	Wytensin (%) n = 109
Dry mouth	7	28
Drowsiness or sedation	12	39
Dizziness	7	17
Weakness	7	10
Headache	6	5

In other controlled clinical trials at the starting dose of 16 mg/day in 476 patients, the incidence of dry mouth was slightly higher (38%) and that of dizziness was slightly lower (12%), but the incidence of the most frequent adverse effects was similar to the placebo-controlled trial. Although these side effects were not serious, they led to discontinuation of treatment about 15% of the time. In more recent studies using an initial dose of 8 mg/day in 274 patients, the incidence of drowsiness or sedation was lower, about 20%.

Other adverse effects were reported during clinical trials with Wytensin but are not clearly distinguishable from placebo effects and occurred with a frequency of 3% or less:
Cardiovascular—chest pain, edema, arrhythmias, palpitations.
Gastrointestinal—nausea, epigastric pain, diarrhea, vomiting, constipation, abdominal discomfort.
Central nervous system—anxiety, ataxia, depression, sleep disturbances.
ENT disorders—nasal congestion.
Eye disorders—blurring of vision.
Musculoskeletal—aches in extremities, muscle aches.
Respiratory—dyspnea.
Dermatologic—rash, pruritus.
Urogenital—urinary frequency, disturbances of sexual function.
Other—gynecomastia, taste disorders.

Drug Abuse and Dependence
No reported dependence or abuse has been associated with the administration of Wytensin.

Overdosage
Accidental ingestion of Wytensin caused hypotension, somnolence, lethargy, irritability, miosis, and bradycardia in two children aged one and three years. Gastric lavage and administration of pressor substances, fluids, and oral activated charcoal resulted in complete and uneventful recovery within 12 hours in both patients.

Since experience with accidental overdosage is limited, the suggested treatment is mainly supportive while the drug is being eliminated from the body and until the patient is no longer symptomatic. Vital signs and fluid balance should be carefully monitored. An adequate airway should be maintained and, if indicated, assisted respiration instituted. There are no data available on the dialyzability of Wytensin.

Dosage and Administration
Dosage with Wytensin should be individualized. A starting dose of 4 mg twice a day is recommended, whether Wytensin is used alone or with a thiazide diuretic. Dosage may be increased in increments of 4 to 8 mg per day every one to two weeks, depending on the patient's response. The maximum dose studied to date has been 32 mg twice daily, but doses as high as this are rarely needed.

How Supplied
Wytensin® (guanabenz acetate) Tablets, Wyeth®, are available in the following dosage strengths:

4 mg, NDC 0008-0073, white, round tablet marked "WYETH" and "73", in bottles of 100.

8 mg, NDC 0008-0074, white, round, scored tablet marked "WYETH" and "74", in bottles of 100.

Keep bottles of Wytensin Tablets tightly closed.
Dispense in tight containers.
Protect from light.

Issued August 17, 1982

Immune Reactions in Tuberculous and Chronic Constrictive Pericarditis

Clinical Data and Diagnostic Significance of Antimyocardial Antibodies

BERNHARD MAISCH, MD, STEFANIE MAISCH, MD, and KURT KOCHSIEK, MD

Humoral immune reactions were analyzed in 12 patients with exudative tuberculous pericarditis, 10 patients with constrictive pericarditis due to former tuberculosis, 10 patients with viral pericarditis, 20 patients with pulmonary tuberculosis, and 98 healthy donors. Pericarditis occurred in 12.5% of the patients with tuberculosis, whereas the incidence of tuberculosis in the 149 patients with pericarditis was 8%. Repeated pericardial puncture and pericardial effusions of greater than 500 ml with impending cardiac tamponade had to be performed in 4 patients. Clinical data indicated probable myocardial involvement in 4 of 12 patients.

Antimyolemmal antibodies, which are a muscle-specific subtype of antisarcolemmal antibodies, were found in all patients with exudative tuberculous pericarditis and viral perimyocarditis, in only 1 of 12 patients with constrictive pericarditis, and in no patient with pulmonary tuberculosis. Antifibrillary antibodies—primarily of the antimyosin type—were missed in patients with viral heart disease but were demonstrated in 75% of patients with tuberculous pericarditis.

Only sera with complement-fixing antimyolemmal antibodies of the IgG type in titers greater than 1:40 induced cytolysis of vital adult heterologous cardiocytes isolated and enriched by silica sol gradient centrifugation. These findings suggest not only that antimyolemmal antibodies are diagnostic indicators of perimyocardial involvement in tuberculous pericarditis, but also that they may play a significant role in its pathogenesis.

In a number of chronic bacterial infections, including chronic granuloma-forming diseases such as mycobacterial infections, evidence of an immunologic basis for clinical manifestations has been accumulated. In infections by Mycobacterium leprae, cellular immune reactions are positively[1] and humoral antibody levels are negatively related to the clinical spectrum[2] or to the severity of clinical manifestations of leprosy.[3,4] In tuberculosis, humoral antibody levels are also inversely proportional to the variables of cell-mediated immunity,[5–7] whereas some manifestations such as erythema nodosum are most likely mediated by immune complexes[8] or may be HLA-linked.[9] Neither humoral nor cellular immune reactions have been investigated in patients with pericardial manifestations of tuberculosis.

A 5 year follow-up study was performed to investigate clinical manifestations and humoral immune reactions in patients with tuberculosis pericarditis and compare their immunologic effector mechanisms with those in patients with viral perimyocarditis,[10–12] in patients with pulmonary tuberculosis alone, and in healthy subjects.

Methods

Patients and sera: The sera of 12 patients with exudative tuberculous pericarditis and of 10 patients with constrictive pericarditis (the underlying cause of which was previously tuberculous pericarditis) were compared with the sera of 20 patients with pulmonary tuberculosis without pericardial or myocardial involvement. Acid-fast tubercle bacilli were secured in all 12 patients with tuberculous pericardial effusion and in 20 patients with pulmonary manifestations only; the cause of constrictive pericarditis had to be determined partly

from old records and anamnestic data. Pericardial constriction was demonstrated by right heart catheterization.

Ninety-eight healthy patients with all blood types and 10 patients with Coxsackie B-myocarditis, on whom data have been published,[10] served as control subjects.

Immunologic investigations: All studies were performed in sera stored at −25°C for up to 5 years. Indirect immunofluorescence was carried out on cryostat sections and air-dried morphologically intact cardiocytes.[10] A modification of the indirect technique[13] was performed using operatively resected myocardium from patients with congenital heart disease (blood group 0). Skeletal muscle, kidney, homologous thyroid gland, uterus and skin, heterologous (rat) liver, esophagus, and stomach were also used. After testing with polyspecific fluorescein-isothiocyanate (FITC)-labelled antiserum ($F[ab]_2$ fragments, H- and L-chain specific: fluorescence/protein (F/P) molar ratio 2.5 ± 1.5, total protein content 23 to 25 mg/ml, dilution 1:10, Behring) immunoglobulin class specificity was analyzed with monospecific FITC-labeled antisera ($F[ab]_2$ fragments, H- and L-chain specific, Behring) and anti-C_3 antiserum (Behring). The antimyolemmal subtype of antisarcolemmal antibodies was determined in isolated cardiocytes, which were deprived of their basement membrane by treatment with collagenase[10]: Vital cardiocytes were allowed to settle in a cylindrical chamber, air-dried and fixed with acetone for 20 minutes. Indirect immunofluorescence was carried out as described earlier.

Antibodies were classified either as muscle-specific or non–tissue-specific. Subtypes of the muscle-specific antibodies included those directed against the sarcolemmal (ASA) and myolemmal (AMLA) membrane, against muscle fibrils (AFA) and the contractile proteins myosin and actin, or against interfibrillary substance (IFA) (Fig. 1). Tissue-nonspecific antibodies found in this study were antinuclear antibodies (ANA), smooth muscle antibodies (SMA), antimitochondrial antibodies (AMA), and antibodies directed against capillaries and the endothelium of small vessels (AEA). A heterologous renal tubular immunofluorescent pattern associated with a positive antisarcolemmal and antiendothelial reaction was attributed to heterophil antibodies and was therefore excluded. Antibodies against double-stranded desoxyribonucleic acid were tested radioimmunologically (Amersham).

Assays of antibody-mediated target cell lysis (AMC): Vital cardiocytes were isolated according to Powell and Twist[14] and enriched to more than 90% vital cells by continuous silica sol gradient centrifugation.[10] Vitality was judged according to shape (cylindrical = vital and spherical = nonvital) and the exclusion of trypan blue.

Assays:

1. Two hundred μl of cardiocytes in a modified Krebs-Ringer solution (NaCl 120.5, NaH/CO_3 13.1, KCl 2.6, KH_2PO_4 1.18, $MgSO_4$ 1.18, CaCl 0.55, and glucose 11.1 mmol/liter and 0.1% [weight/volume] Pentax Fraction V bovine serum albumin type F [Sigma]) in a concentration of 5×10^4 cells/ml were placed in the wells of microtiter plates (Falcon multiwell 3008). Additions were 50 μl decomplemented serum and 50 μl of human complement (fresh normal serum). After shaking for 10 seconds, 200 to 400 cells/well were counted and then incubated at 37°C (5% CO_2). The percentage of vital cells was assessed again after 12 and 24 hours. The assay was done in duplicate for each serum with a 5% limit of tolerance in counting between both samples. For each duplicate the half-life of the cardiocytes present in the patient's serum (t_{50i}) was compared with the half-life of cardiocytes in an identical representative control serum (t_{50c}). The cardiocyte index of antibody mediated cytolysis (CI_{AMC}) was calculated using the following formula: $CI_{AMC} = t_{50i}/t_{50c}$. In normal subjects (n = 80) $CI_{AMC} = 0.92 \pm 0.07$ (mean ± standard deviation). Effective cytolysis was assumed when CI_{AMC} was less than 0.8.

2. Rat hepatocytes were used in control assays. They were obtained by isolation procedures already described.[14] Assays of hepatocytolysis were carried out with hepatocytes resuspended in minimal essential medium (MEM) containing Earl's Spinner BSS with Glutamin and 20 mmol HEPES (pH 7.2) in concentrations of 5×10^4 cells/ml. The index of hepatocytolysis (HI_{AMC}) of 12 control sera was 0.95 ± 0.12 (mean ± standard deviation).

Statistical analysis: Results are given as means ± standard deviation (SD). After testing the homogeneity of variances with the Fisher test, a standard *t* test was used to evaluate the significance of differences among groups of patients. For paired samples the corresponding *t* test was used. All tests were two-tailed. In the case of inhomogeneity of variances a Welch test was employed.

The significance of correlations was tested by regression analysis. The regression was tested for linearity by variance analysis. All other statistical comparisons were performed with the chi-square test using Yates' correction factor.

Results

Clinical data: The incidence of both exudative tuberculous and constrictive pericarditis due to former tuberculous pericarditis was 2 patients/year. In the 5 years of this investigation, 12 of 97 patients with tuberculosis had pericardial effusions. However, the 12.4%

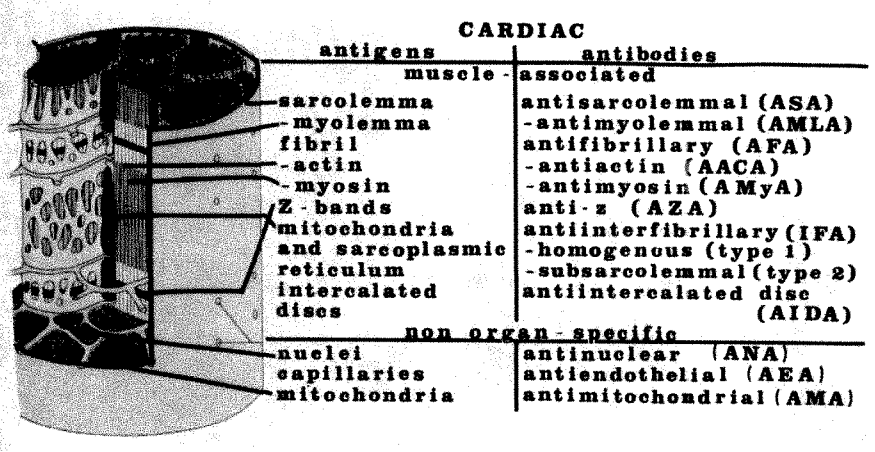

FIGURE 1. Cardiac antigens and their respective cardiac autoantibodies.

frequency of tuberculous pericarditis exceeds the natural incidence of pericarditis in patients with tuberculosis substantially because patients with pericardial symptoms were transferred from other hospitals. Thus, in 8% of all patients with pericarditis (n = 49) admitted to our hospital in 1976 to 1981—patients with postpericardiotomy and postinfarction syndromes were excluded—tuberculosis was the underlying cause. Thirteen patients had pericarditis of viral origin (10 Coxsackie B, 2 influenza, and 1 mumps), 10 had uremia, and the cause in the remaining patients was unresolved. Patients with constrictive pericarditis were seen either before pericardectomy (3 patients), because of cardiac insufficiency or coronary heart disease (4 patients) and/or because of diabetes mellitus (3 patients).

TABLE I Anamnestic and Clinical Data in Exudative and Constrictive Tuberculous Pericarditis

	Number Positive

PPD = purified protein derivative.

Male patients prevailed in both groups (Table I). Three of 12 patients with tuberculous pericarditis and 2 of 10 with constrictive pericarditis were of foreign (Mediterranean) nationality.

Diabetes mellitus and alcoholism were the most important risk factors of tuberculosis (Table I). Frequent nonspecific symptoms were fatigue, fever, and sweats in exudative pericarditis; leading cardiac symptoms included dyspnea and precordial pain (Table I). Pulmonary manifestations of tuberculosis were observed regularly followed by mediastinal lymphadenitis and exudative pleuritis. A diagnosis of probable myocarditis was made in 4 patients by electrocardiography, echocardiography, or both. Electrocardiographic features observed regularly were tachycardia and ST-T segment alterations showing either elevation, T-wave depression or negative T waves in exudative pericarditis. Low voltage in limb leads was seen in only 50% of patients, and atrial flutter was found in 3 of 10 patients with constrictive pericarditis (Table II). Pericardial effusion of greater than 500 ml was seen in 6 patients, necessitating pericardial puncture in all and consecutive operative treatment in 4 patients due to impending cardiac tamponade. Pericardectomy in patients with constrictive pericarditis had to be performed in only 3 cases.

Autoantibodies in exudative tuberculous pericarditis: The presence of antisarcolemmal antibodies and their muscle-specific subtype of antimyolemmal antibodies (Fig. 2) in all patients was the characteristic immunologic feature of acute tuberculous pericarditis and of viral pericarditis (Table II). ASA was associated with non–organ-specific antiendothelial and antibasement membrane antibodies in 42% of patients. Because the cardiac sarcolemma is composed of at least 3 different layers—the basement membrane, reticulin, and the myolemma itself—and many more antigenic moieties, antisarcolemmal and antiendothelial antibodies were most likely directed against antigenic sites shared between connective tissue and the sarcolemmal basement membrane.

Muscle-specific antimyolemmal antibodies, however, which were observed in all patients, could only be distinguished on vital or acetone-fixed cardiocytes, which have been deprived of their basement membrane by treatment with collagenase (Fig. 2).

The frequency of antisarcolemmal and antimyolemmal antibodies was significantly higher in patients with exudative tuberculous pericarditis than in those with pulmonary tuberculosis ($\chi^2 = 22.08 > 10.83 = \chi^2_{0.001}$; 2p <0.001), constrictive pericarditis ($\chi^2 = 13.0 < 10.83 = \chi^2_{0.001}$; 2p <0.001), and normal subjects (n = 98; 2 only positive for antimyolemmal antibodies; $\chi^2 = 92.36$; 2p <0.00001). Antimyolemmal antibodies were of the IgG class in 10 of 12 patients and of the IgM class in only 4 patients. They fixed complement in 5 patients' sera.

Antifibrillary antibodies were secreted in 75% of patients with exudative pericarditis, this occurring significantly more often than in constrictive pericarditis ($\chi^2 = 9.3$; 2p <0.01) and in control subjects ($\chi^2 = 47.03$; 2p <0.00001). Antimyosin antibodies (Fig. 3) prevailed in 8 of the 9 patients. They are the serologic marker

TABLE II Autoantibodies in Exudative Tuberculous Pericarditis and Chronic Constrictive Pericarditis (1976 to 1981)

Antibody Type	Percent Positive			
	Tuberculous Pericarditis (n = 12)	Chronic Constrictive Pericarditis (n = 10)	Tuberculosis Without Pericarditis (n = 20)	Viral Pericarditis Coxsackie B (n = 10)
Muscle-specific				
Antisarcolemmal (ASA)	100	10	10	100
Antimyolemmal (AMLA)	100	10	0	90
Antifibrillary (AFA)	75	10	10	10

Antimitochondrial (AMA)	33	10	10	10

Healthy normal subjects (n = 98): all antibodies less than 8%.

discriminating best between tuberculous (positive) and viral pericarditis (negative), since in the latter cases they were missed frequently.

Autoantibodies in constrictive pericarditis, pulmonary tuberculosis, and control subjects: Frequency of muscle-specific and non–organ-specific autoantibodies in patients with chronic constrictive pericarditis and in those with pulmonary tuberculosis without pericarditis did not significantly exceed the frequency in normal subjects (n = 98) (Table II).

Demonstration of antibody-mediated cytolysis: Cytolytic serum activity against vital heterologous cardiocytes was closely related to the presence of antimyolemmal antibodies in titres greater than 1:20. Only 1 patient's serum, which did not demonstrate antimyolemmal antibodies, induced cytolysis nonspecifically; in all other cases cytolytic activity increased proportionally with the reciprocal AMLA titer. Whereas 1 of 8 sera with AMLA titers of 1:20 induced cytolysis in the presence of complement, 2 of 3 with a titer of 1:40 and 3 of 4 with a titer of 1:80 were cytolytic (Fig. 4). By linear regression analysis between the reciprocal AMLA titers and the index of antibody-mediated cardiocytolysis, a fair correlation between both variables was established ($y = -0.0045x + 1.02$; $r = 0.62$).

In 4 of 5 patients with pericarditis, whose sera were cytolytic, myocardial involvement was made likely by electrocardiographic criteria (ST-T segment displacement, atrial flutter, and heart block) and by cardiomegaly. In these patients additional heart disease such as coronary and valvular heart disease could be excluded.

The following additional experimental data also support an antibody-mediated process and make unspecific cardiocytolysis in vitro unlikely:

1. Only antimyolemmal antibodies bind to vital cardiocytes as observed by indirect immunofluorescence (n = 10). Sera containing antifibrillary antibodies only

FIGURE 2. Demonstration of antimyolemmal antibodies by indirect immunofluorescence using acetone-fixed rat cardiocytes. A linear staining is observed along the glycocalix or myolemma.

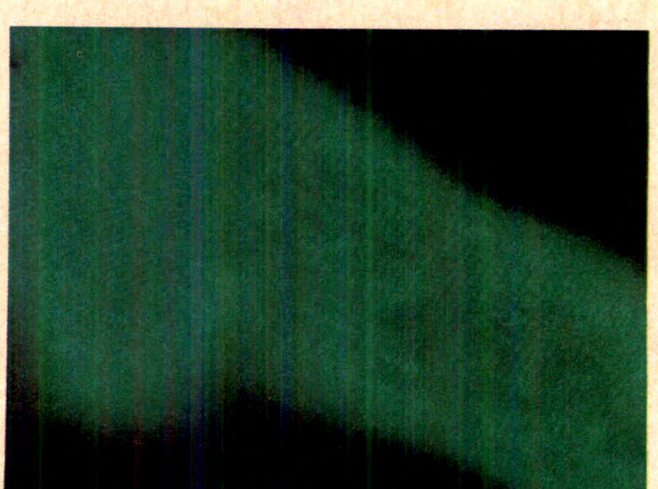

FIGURE 3. Demonstration of antifibrillary antibodies of the antimyosin type. The thick filaments are stained by this patient's serum with tuberculous perimyocarditis. The antigen used for indirect immunofluorescence was acetone-fixed rat cardiocytes.

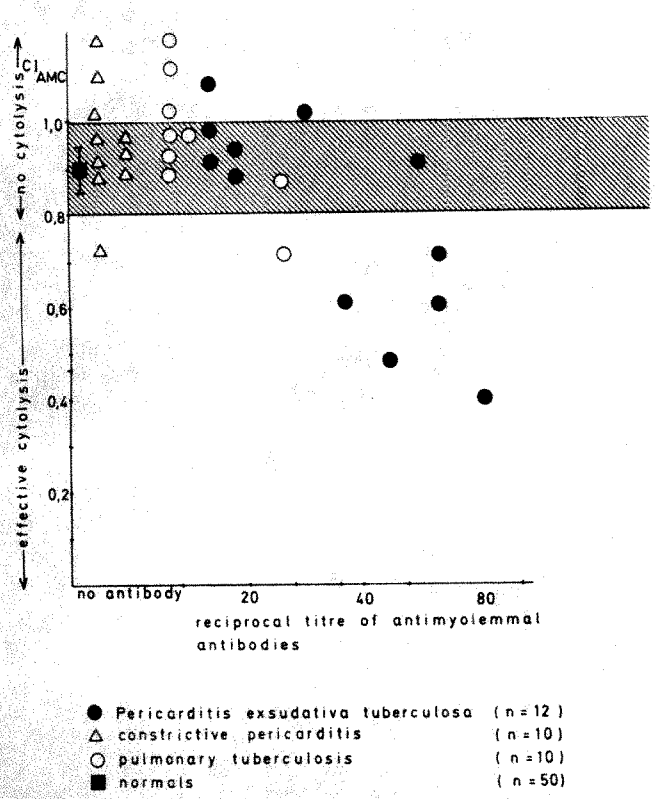

FIGURE 4. Correlation between reciprocal titres of antimyolemmal antibodies and antibody mediated cytolysis (AMC). The degree of AMC is expressed by the cardiocyte index of AMC (CI_{AMC}). Effective cytolysis can be expected if CI_{AMC} is lower than 0.8. It could be demonstrated that sera containing antimyolemmal antibodies in high titres induced cytolysis of vital adult cardiocytes in patients with exudative tuberculous pericarditis. In contrast, no cytolysis was observed in AMLA-negative sera of patients with constrictive pericarditis, in patients with pulmonary tuberculosis, and in normal subjects.

gave no intracellular staining when incubated with *vital* myocytes.

2. Antimyolemmal antibodies did not stain the membrane of other target cells such as rat hepatocytes (n = 10).

3. When sera, which contained antimyolemmal antibodies, were absorbed with a pellet of vital cardiocytes (n = 8), they became AMLA-negative. Before absorption, strong cytolytic activity with an index of cytolysis (CI_{AMC}) of 0.58 ± 0.06 was demonstrated. After absorption the CI_{AMC} had normalized by reaching 0.89 ± 0.07. Absorption of the sera with equal amounts of rat hepatocytes did not significantly alter the immunofluorescent pattern of cardiocytes nor the cytolytic serum activity. Sera containing antimyolemmal antibodies in titres of 1:40 and 1:80 were not cytolytic to different target cells such as rat hepatocytes (n = 5; HI_{AMC} = 0.96 ± 0.15, as compared with 0.95 ± 0.12 in 12 normal controls).

4. In the absence of complement no cytolytic activity of AMLA-positive sera against cardiocytes was observed. This indicates that complement had to be bound to the antibody for the cytolytic reaction (n = 5).

5. Immune complexes of aggregated IgG (A-IgG) in concentrations of 10 to 250 μg/ml did not adhere to the membrane of vital and acetone-fixed cardiocytes (n = 5), nor did they induce cytolysis of cardiocytes (CI_{AMC} = 0.97 ± 0.04 for 50 μg A-IgG/ml, and 0.94 ± 0.08 for 250 μg A-IgG/ml).

Discussion

Clinical data: In our area tuberculosis remained the most frequent single infective pericarditic pathogen, followed by viral perimyocarditis of the Coxsackie B type.[12,15] Bacterial pericarditis other than from tuberculosis was found only once in a patient with staphylococcal perimyocarditis. Pericarditis after cardiac surgery was much more common in our patients[16–18] than in any single viral or bacterial pericardial disease. However, it is controversial whether the postpericardiotomy syndrome is caused by autoimmune reactions alone[18,19] or occurs in the presence of an infection, which may be viral.[20]

The clinical manifestations of tuberculous pericarditis in our patients does not substantially differ from the findings in previous studies[21] with respect to male preponderance, nonspecific and cardioselective symptoms, risk factors of tuberculosis, clinical manifestations, and electrocardiographic and laboratory findings. In addition to pericardial involvement, clinical data indicated that myocardial involvement was likely in 33% of our patients. With the exception of pericarditis after radiation in Hodgkin's disease,[22] repeated pericardial puncture or pericardiocentesis, or both, had to be performed most often in patients with tuberculous pericarditis.

Diagnostic and pathogenetic significance of antimyocardial antibodies: Muscle- and non–organ-specific autoantibodies have been described in several cardiac diseases such as rheumatic carditis,[23] viral perimyocarditis,[11,12,15] infective endocarditis,[24,25] postpericardiotomy,[16,17,19,20] and postinfarction syndromes.[26–28] These antibodies have not been reported in patients with tuberculous pericarditis. Non–organ-specific autoantibodies, however, were described in patients with mycobacterial infection without pericardial involvement, such as leprosy.[29] In tuberculosis, autoantibodies were reported only in animal models such as rabbits infected with acid-fast bacilli: Non–organ-specific antibodies were directed against a variety of antigens present in liver, spleen, kidneys, heart, lung, and lymph nodes.[30]

Our studies clearly demonstrate the presence of antisarcolemmal antibodies and their muscle-specific subtype, the antimyolemmal antibodies, in exudative tuberculous pericarditis. Together with antifibrillary antibodies, they indicate perimyocardial manifestation in tuberculosis because they were not found in patients with pulmonary tuberculosis. As compared with patients with viral pericarditis, whose sera also contained antimyolemmal antibodies, the additional presence of antifibrillary antibodies was the discriminating factor adding to specificity. Both antibodies were also markers of disease activity: In constrictive pericarditis due to previous tuberculous pericarditis the incidence was only 10% and titers were low.

Antisarcolemmal antibodies can be directed not only against the myolemma but also against the non–organ-specific moieties of the sarcolemmal basement membrane. A cross-reaction of antisarcolemmal antibodies with moieties of connective tissue of the pericardial sac and the basement membrane of the myocardial cell is therefore very likely. However, their muscle-specific subtype, the antimyolemmal antibodies, were found in all patients with tuberculous pericarditis.

Whereas antisarcolemmal antibodies are heterogeneous, antimyolemmal antibodies appear cardiospecific. In this study heterophil antibodies[31] and isoantibodies against blood group substances[32] were excluded by the use of both homologous (human blood group 0) and heterologous myocardium (rat/bovine) and the elimination of antibody patterns typical for heterophil antibodies. The muscle-specific antimyolemmal antibody pattern was identified by the use of cardiac muscle cells deprived of reticulin and collagenous parts of the basement membrane[33] after treatment with collagenase.[10,11]

We could also exclude nonspecific absorption of immune complexes through their Fc-receptors by cardiac antigens from negative tests with aggregated IgG (unpublished data).

The presence of complement-fixing muscle-specific antimyolemmal antibodies of the IgG type most likely indicates myocardial involvement in tuberculous pericarditis. All 4 patients with clinical evidence of myocarditis in tuberculous pericarditis demonstrated antibody-mediated cytolysis induced by complement and antimyolemmal antibodies in titers of more than 1:40. Further studies have to be performed to determine whether antimyolemmal antibodies in tuberculous pericarditis are cross-reacting to antigenic moieties of the pathogenic agent involved, as has been demonstrated in rheumatic fever[23,34,35] and viral perimyocarditis.[11] In previous studies performed in our laboratory it could be established that subgroups of antimyolemmal antibodies and cytolytic activity against vital cardiocytes can be absorbed completely with the respective viral antigen (in Coxsackie B, influenza, and mumps perimyocarditis).[11]

Moreover, our data suggest that cytolysis of vital cardiocytes is induced by complement-fixing antimyolemmal antibodies. Cardiocytolysis was present only in sera containing antimyolemmal antibodies. Their titers correlated with the cytolytic serum activity.[11] An additional effect of cytotoxic serum factors[36,37] which do not necessarily belong to the immunoglobulins cannot be ruled out completely. Cardiocytolysis was effective only in the presence of antibody and complement since it was not observed when cardiocytes were incubated with decomplemented sera only.[11]

Our studies favor the possibility that antibody-mediated cytolysis in vitro represents a model of the secondary immune process that could be operative in vivo. With the exception of antimyolemmal antibodies all other antimyocardial or non–organ-specific antibodies do not affect vital cardiac cells in vitro and vivo. They are most likely "innocent bystanders."

The occurrence of antimuscle antibodies directed against the myolemma and fibrils has been temporarily related to tuberculous pericarditis. Because there was clinical evidence of additional myocardial involvement in many patients, antimyolemmal and antifibrillary antibodies are indicators of myocardial inflammation as well. Moreover, cardiocytolysis mediated by AMLA-positive sera in the presence of complement in vitro indicates that a secondary immune process may be operative in vivo. Cytolytic antimyolemmal antibodies may be both temporarily and causally related to perimyocarditis in tuberculosis.

In several studies[5,7] the complex immunopathogenesis of tuberculosis has primarily been based on cell-mediated immune reactivity. Humoral antibodies were inversely proportional to the variables of cell-mediated immunity.[6] Our investigations demonstrate that in tuberculous pericarditis, B-cell effector mechanisms such as antimyolemmal antibodies are operative regularly. It may be concluded from these data that tuberculous pericarditis occurs predominantly in patients with a partial defect of cell-mediated immunity. Further studies are underway to investigate cell-mediated immunity, the relevance of host resistance, and its possible genetic control in patients with tuberculosis and perimyocardial inflammation.

Constrictive Pericarditis: New Aspects

NOBLE O. FOWLER, MD

The current status of constrictive pericarditis is reviewed with regard to its etiology, physical signs, electrocardiographic findings, and hemodynamic features. Angiographic aspects are also presented. The role and limitations of M-mode echocardiography in this disease are emphasized. The value of other noninvasive studies such as measurement of systolic time intervals, myocardial scanning, and high-speed echocardiography is described. Emphasis is placed on the invasive and noninvasive methods that may be useful in separating restrictive cardiomyopathy from constrictive pericarditis. Methods of treatment, indications for pericardial resection, and the current operative results are commented on briefly.

Constrictive pericarditis is an uncommon disease but an important one. It represents a potentially curable cause of circulatory dysfunction manifested by persistent dyspnea, fatigue, and elevated systemic venous pressure. During the past few years, much new information has appeared concerning the etiology and physiology of constrictive pericarditis. The application of new methods has materially advanced our ability to understand and recognize the physiologic disturbances associated with this disease. This important information concerning etiology, the mechanism of physical signs, hemodynamic features, effects of fluid challenge, systolic time intervals, echocardiograms, and studies with ventriculograms and echocardiograms recorded at fast speed is reviewed herein.

Etiology

During the past few decades, the etiologic background of pericardial disease in general, and of constrictive pericarditis in particular, has changed. Tuberculosis was formerly considered the most common recognizable cause of chronic constrictive pericarditis,[1,2] but acute nonspecific pericarditis may be more common in later series.[3,4] In the series of Wychulis et al.,[4] idiopathic pericarditis was the most common antecedent, but in most cases the cause was unknown. In effusive-constrictive pericarditis, neoplasm, radiation therapy, rheumatoid arthritis, and idiopathic pericarditis are common causes.[5] The long survival of patients with end-stage renal disease has allowed patients with uremic pericarditis to develop constrictive pericarditis in some instances.[6–9] Patients with metastatic neoplasm, including lymphomas, may develop constrictive pericarditis, either because of neoplastic involvement of the pericardium, or because of radiation therapy directed toward the mediastinum. Immunosuppressive therapy has permitted longer survival of patients with connective tissue disease, some of whom have pericardial disease, including constrictive pericarditis. Rheumatoid arthritis has emerged as a not uncommon cause of pericardial constriction.[10–16] Rheumatic fever is still regarded as a rare cause of constrictive pericarditis. Purulent pericarditis may be a complication of connective tissue disease in a patient with impaired host defense mechanisms. Most pericardial infections, including viral infections,[17–19] have the possibility of constrictive pericarditis as a late complication. Intrapericardial bleeding after trauma[20] or diagnostic procedures or pacemaker insertion[21] may be followed by constrictive pericarditis.

Of particular recent interest is the constrictive pericarditis associated with mulibrey nanism. Constrictive pericarditis was found in 8 of 26 patients with this disease; one was reported from the U.S.A. and 3 from Canada.[22] The others reported were from Finland, with the exception of 1 from Egypt. Constrictive pericarditis after radiation therapy directed toward the mediastinum may be delayed for years after such therapy. A recent report[23] of 9 cases of radiation-induced pericardial fibrosis described a delay of 53 to 124 months between the original treatment and the later diagnosis of pericardial disease. In 3 reported cases[24,25] there was a possible relationship of constrictive pericarditis to methysergide therapy. Two reports[26,27] of constrictive pericarditis after Dressler's postmyocardial infarction syndrome have appeared in the literature. The association between congenital atrial septal defect and constrictive pericarditis is recognized but difficult to explain.[3,28–30]

Constrictive pericarditis after cardiac operations is uncommon but is now being recognized. Three cases were reported[31] in 1979 after coronary artery bypass grafting. Three other cases after cardiac valve replace-

ment were reported from New York in 1979[32]; we have had experience with 3 such cases. Marsa[33] reports that 19 instances have now been described. The largest series is that reported by Kutcher et al.[34] from Emory University. They found 11 instances of constrictive pericarditis after about 5,000 cardiac operations; the incidence was 0.21%. Evidence of cardiac constriction was usually present within 3 to 6 months after operation, and in some within a few weeks. A possible relationship between constrictive pericarditis and the use of povidone-iodine pericardial irrigating solution has been raised.

Physical Signs

Cervical veins: A consistent feature of the disease is persistent elevation of systemic venous pressure even after treatment with diuretics, digitalis, sodium restriction, and rest. The frequent presence of Kussmaul's sign in constrictive pericarditis and its absence in cardiac tamponade has been emphasized by Spodick[35] and others.

Paradoxical pulse: A paradoxical arterial pulse (inspiratory decline of systolic blood pressure of 10 mm Hg or greater) is present in nearly every patient with cardiac tamponade associated with pericardial effusion unless there is left ventricular dysfunction, atrial septal defect, or aortic incompetence. This sign is absent in most patients with constrictive pericarditis and indeed was found in only 1 of our last 13 cases, and was of borderline degree in that 1. On the other hand, Wise and Conti[36] found pulsus paradoxus in 10 of 22 cases of constrictive pericarditis, and Wychulis et al.[4] in 40 of 137.

Pericardial knock: Another important physical sign is the pericardial knock sound. This diastolic sound associated with constrictive pericarditis tends to occur earlier in diastole than the normal third heart sound or the S_3 gallop sound associated with myocardial dysfunction. The knock sound interval from the aortic component of the second heart sound is usually 0.06 to 0.10 second rather than 0.12 to 0.16 second as found with third heart sounds and S_3 gallop sounds. The genesis of the pericardial knock sound was studied by Tyberg et al.,[37] who found that the timing of the pericardial knock sound corresponded to that of a sudden and premature plateau of the diastolic left ventricular volume curve, occurring on the average at the time of completion of 85% of the ventricular filling in early diastole. This plateau was missing in 2 patients with constrictive pericarditis who had no pericardial knock sound. In those 2, the rate of ventricular filling was faster than normal in the first 20% of diastole. This study supported the view that the sudden cessation of rapid ventricular filling generates the pericardial knock of constrictive pericarditis. Nicholson et al.[35] reported the knock to be increased by squatting and phenylephrine infusion and eliminated by nitroglycerin therapy.

Electrocardiography

The usual electrocardiogram in constrictive pericarditis shows nonspecific S-T and T abnormalities, and low voltage QRS without patterns of bundle branch block or ventricular hypertrophy. In one study, 6 of over 100 patients had right ventricular hypertrophy,[39] a prevalence of 5%. We[40] reported on a 13 year old patient who had pericardial fibrosis with constriction in the atrioventricular groove leading to a variety of mitral stenosis whose electrocardiogram had evidence of left atrial and right ventricular enlargement in lead V_1—thus stimulating the electrocardiogram of mitral stenosis. Five cases were described with subpulmonary stenosis due to a constricting band of pericardium; right ventricular hypertrophy was reported in 1.[40a]

Hemodynamic Features

Several hemodynamic features of the disease deserve comment. These include angiographic features, the radiologic appearance of the right atrial angiocardiogram, the comparison of ventricular and atrial pressure pulses in constrictive pericarditis and in cardiac tamponade, systolic time intervals, and the results of fluid challenge in patients with occult constrictive pericarditis.

Angiography: Motion of the free wall of the right ventricle showed diastolic restriction in both constrictive pericarditis and in restrictive cardiomyopathy; normal motion of the crista supraventricularis was seen in constrictive pericarditis but not in restrictive cardiomyopathy.[41]

Right atrial angiocardiogram: In constrictive pericarditis the 3 characteristics of the right atrial angiocardiogram are increased thickness of the right atrial wall plus pericardium beyond the normal value of 3 to 5 mm, straightening of the right heart border without the normal lateral convexity, and poor pulsations of the right atrial wall. Although usually present, a typical angiocardiogram may be absent and was not seen in 3 of our last 13 patients with constrictive pericarditis.

Pressure pulse in right atrium and the ventricles: It is well recognized that the characteristic deep *x* and *y* descents in the right atrial pressure pulse and the square root sign in the right and left ventricular pressure pulses are present in nearly every case of constrictive pericarditis and are not found in the typical case of cardiac tamponade. In patients with effusive-constrictive pericarditis, the *x* and *y* descents may not be prominent at first, but with removal of the fluid the hemodynamic effects of the underlying constrictive process are unveiled; then the *x* and *y* descents may be prominent and the square root sign appears.

Systolic time intervals: Nine cases of constrictive pericarditis were studied.[42] Left ventricular ejection time (LVET) was shortest in patients with congestive heart failure, averaging 359.9 ms; it averaged 392.3 ms in constrictive pericarditis and 403.3 ms in normal subjects. Mean PEP (preejection period)/LVET was 0.48 in patients with congestive heart failure, 0.31 in those with constrictive pericarditis, and 0.28 in normal subjects.

Results of fluid challenge: Bush et al.[43] in 1977 reported the effects of a volume challenge produced by infusion of 1 liter of normal saline solution during a period of 6 minutes in patients with occult constrictive

pericardial disease, in those with cardiomyopathy, and in a small group of normal subjects. In normal subjects, mean right atrial and pulmonary wedge pressure did not rise more than 3 mm Hg with the fluid challenge. In those with occult constrictive pericardial disease, postinfusion levels of right atrial and pulmonary wedge pressure were comparable to each other and there was diastolic equilibration of right atrial and pulmonary wedge pressure which had been absent before. All patients with occult constrictive pericarditis developed an *x-y* right atrial pressure contour during volume expansion, whereas this did not occur in normal subjects. In patients with myocardial disease, volume expansion did not lead to equilibration of pulmonary wedge and right atrial pressure, and only a few exhibited *x-y* contour of the pressure pulse in the right atrium.

Echocardiography

There is no single diagnostic or specific echocardiographic pattern in constrictive pericarditis. Gibson et al.[44] reported abnormal ventricular septal motion in 8 of 10 patients with constrictive pericarditis. Diminished systolic motion was followed by unusual posterior motion in diastole. In a review of our 12 patients who had echocardiograms, Peter Engel in our laboratory found abnormal systolic septal motion in 5, abnormal diastolic septal motion in 4, thickened pericardium in 6 of 11, and left ventricular posterior wall diastolic flattening in 8 of 11.

Schnittger et al.[45] found evidence of pericardial thickening in their cases of constrictive or constrictive-effusive pericarditis. Six of 14 patients with constrictive pericarditis had abnormal ventricular septal motion, and 9 of 14 had diastolic flattening of left ventricular posterior wall motion.

Voelkel et al.[46] reported that diastolic motion of left ventricular posterior endocardium was less than 1 mm in 11 of 12 patients with constrictive pericarditis; it was 1.5 to 4.0 mm in 10 normal subjects. Horowitz et al.[47] reported systolic septal thickening of 18 to 45% in 11 patients with constrictive pericarditis, and 9 to 11% in 6 patients with restrictive cardiomyopathy. Mintz et al.[48] reported a lack of respiratory variation in inferior vena caval echocardiographic dimension in patients with constrictive pericarditis or right ventricular dysfunction. In another study[49] computer tomography was of value in recognizing constrictive pericarditis or pericardial effusion in some patients whose echocardiograms were not satisfactory for this purpose.

Distinction From Restrictive Cardiomyopathy

Considerable interest has focused on the problem of separating restrictive cardiomyopathy, especially that due to amyloid disease, from constrictive pericarditis. The patient with restrictive cardiomyopathy may have a paradoxical arterial pulse and persistent elevation of systemic venous pressure with prominent *x* and *y* descents, and may have normal ventricular dimensions on the echocardiogram. Studies of filling patterns of the left ventricle by 2 means, (1) angiography and (2) high speed echocardiography, may aid in the differentiation of constrictive cardiomyopathy and constrictive pericarditis. Tyberg et al.[50] studied by angiography 7 normal subjects, 7 patients with constrictive pericarditis, and 4 with cardiac amyloid disease. The critical separation among the 3 groups was achieved at 50% of diastole. In patients with constrictive pericarditis 85% of left ventricular filling was achieved by the completion of 50% of diastole; this value separated the cardiac filling pattern in constrictive pericarditis from that in normal subjects (65% of filling of the left ventricle by completion of 50% of diastole) and that in 4 patients with amyloid disease (50% of filling of the left ventricle by completion of 50% of diastole). Meyer et al.[51] studied the rate of left ventricular filling in these 3 conditions by high speed echocardiography and found that the rate of left ventricular filling was more rapid in constrictive pericarditis than in restrictive cardiomyopathy. The interval from minimal left ventricular dimension (end-systole) to maximum left ventricular filling was 0.05 ± 0.01 second in constrictive pericarditis and 0.11 ± 0.03 second in restrictive cardiomyopathy.

Wizenberg et al.[52,53] studied 10 patients with cardiac amyloidosis, each of whom had symmetrical left ventricular posterior wall and septal hypertrophy on echocardiography. Six of 7 had an increased PEP/LVET ratio (0.46 to 0.83). Each exhibited decreased systolic thickening of the septum and posterior wall. Each of the 10 patients had a diffuse myocardial uptake of technetium pyrophosphate (4+ in 9 and 3+ in 1).

Tei et al.,[54] in a preliminary communication, reported an echocardiographic study of 12 patients with restrictive cardiomyopathy and 13 with constrictive pericarditis. An abnormal atrial systolic notch of interventricular septal motion was found in 7 of 8 patients with constrictive pericarditis who had sinus rhythm and in none of the 12 with restrictive cardiomyopathy.

Treatment

The treatment for chronic constrictive pericarditis is generally considered to be pericardiectomy, for which operation the current mortality rate is 4 to 6%.[4,55,56] However, in some series[56] the death rate was 20%. Culliford et al.[55] presented an argument for resection of the pericardium from all surfaces of the heart and intrapericardial vessels. The administration of digitalis, sodium restriction, and diuretics may be helpful in some instances,[56] especially when there is impairment of myocardial function. When the operation is adequately carried out, two thirds or more of the patients show major long-term improvement.[4,55] In some instances immediate pericardiectomy is not essential. In patients who have mild or no functional impairment, operation may be deferred since the process ordinarily progresses very slowly. When operation is delayed for years, one must consider the possibility of a more difficult operation later with a higher risk of mortality, as well as increasing damage to the myocardium.

The place of operative treatment in the management of occult constrictive pericarditis[57,58] *remains unsettled.* Since these patients, who have little or no resting hemodynamic impairment, may usually be ex-

pected to do well for an extended period of time, there is a question as to whether or not an operation of more than minimal risk should be undertaken to relieve a condition that is not life-threatening.[59]

Other groups of patients with constrictive pericarditis may require extensive evaluation before a decision is made concerning pericardiectomy. Among these are elderly patients with minimal impairment or extensive pericardial calcification, those with other diseases limiting life expectancy or quality of life, and those with a high likelihood of myocardial damage, such as patients with radiation-induced pericarditis.

Echocardiographic Study of Right Ventricular Wall Motion in Cardiac Tamponade

PETER J. ENGEL, MD, HENRY HON, MD, NOBLE O. FOWLER, MD, and SANDI PLUMMER, RCT

Twenty-one patients had M-mode echocardiographic recordings during cardiac tamponade. Seventeen of 21 had posterior motion of right ventricular endocardium at 0.05 second or longer after opening of the mitral valve. Sixteen of 17 patients with a large pericardial effusion without cardiac tamponade had posterior right ventricular wall motion that ceased at 0.05 second or less after opening of the mitral valve. The finding of early diastolic posterior motion of the right ventricular wall may signify diastolic collapse of the right ventricle and aids the echocardiographic identification of cardiac tamponade.

Echocardiography is the most sensitive tool for the detection of pericardial effusion. As little as 15 ml of pericardial fluid can be detected with this technique.[1] Large effusions are also easily identified. Determination of the hemodynamic consequences of pericardial effusion by echocardiography has proved more challenging. Preliminary reports[2,3] suggest that persistence of systolic posterior motion of the right ventricular wall into diastole may serve as an echocardiographic marker of cardiac tamponade. The purpose of the present study was to critically examine the usefulness of this sign in a large series of patients with cardiac tamponade examined with echocardiography.

Methods

Patients: The clinical records of all patients with the diagnosis of pericardial effusion with cardiac tamponade seen at our institution between 1972 and 1980 were reviewed. Cardiac tamponade was defined as inspiratory decline greater than 10 mm Hg in systolic arterial blood pressure and elevated systemic venous pressure in the presence of pericardial effusion. If a drainage procedure was performed (21 patients), then the elevated venous pressure and pulsus paradoxus improved or resolved.

Fifty-five such patients were identified, of whom 24 were examined with M-mode echocardiography and formed the study group. A control group of M-mode echocardiograms consisted of 17 unselected studies from patients with a large pericardial effusion without clinical evidence of tamponade.

From the Department of Internal Medicine, Division of Cardiology, University of Cincinnati College of Medicine, Cincinnati, Ohio. Manuscript received November 17, 1981; revised manuscript received April 12, 1982, accepted April 26, 1982.

Address for reprints: Peter J. Engel, MD, University of Cincinnati College of Medicine, Division of Cardiology, 231 Bethesda Avenue, Room 3354, Cincinnati, Ohio 45267.

Echocardiography: The studies were performed with either a Smith-Kline Ekoline 20 or an Irex System II instrument using standard techniques. Strip chart recordings were made at either 50 or 100 mm/s paper speed.

Motion of the right ventricular endocardium was analyzed using both the electrocardiogram and mitral valve motion for reference. The point in time when the right ventricular posterior motion ceased was termed the X point (Fig. 1). Note was made of the relation of the X point to the electrocardiographic T and P waves. For quantitation of this relation, the interval between the preceding R wave and the X point was divided by the preceding R-R interval to form the ratio R-X/R-R.

Particular attention was paid to the interval between mitral valve opening and the X point (MVO-X). If the mitral valve opening preceded the X point, a positive value is obtained for MVO-X. If the X point occurred before mitral valve opening, the MVO-X interval is negative. If no anterior echo-free space was apparent, the study was not included in subsequent analysis. The minimal right ventricular diastolic dimension was measured as the distance between right ventricular endocardium and the right side of interventricular septum at the X point.

Analysis of data: The echocardiographic measurements were made independently by 2 observers unaware of the clinical status of the patients. Major discrepancies were resolved by consensus. The measurements reported represent the average of the 2 independent measurements in each case. The sensitivity of a test for a condition is defined as the probability that it will be positive in patients with the condition; the specificity is defined as the probability that the test will be negative in patients without the condition. The predictive value of a positive test is defined as the probability that the condition is in fact present, given a positive test result.

Results

Clinical diagnosis: Forty-one patients were studied with M-mode echocardiography. Twenty-four had clinical or hemodynamic evidence, or both, of cardiac

tamponade, whereas 17 had a large pericardial effusion without evidence clinically or hemodynamically of cardiac tamponade. Of the 24 patients with tamponade, 12 had malignant pericardial effusion, 3 had an effusion that was considered viral or idiopathic in origin, 2 had tuberculous pericarditis, 3 had uremic pericarditis, and 1 each had bacterial pericarditis, systemic lupus erythematosus, postpericardiotomy syndrome, and aortic dissection.

MVO-X interval: One patient in the group with effusion without tamponade and 3 in the group with tamponade had echocardiograms in which the X point could not be identified due to the absence of anterior pericardial effusion; these studies were excluded from subsequent analysis. The mean value (± standard error of the mean) for the mitral valve opening-X point (MVO-X) interval was −0.04 ± 0.01 second in the group without tamponade and +0.09 ± 0.02 second in the tamponade group. Seventeen of 21 patients with tamponade had an MVO-X interval of +0.05 second or greater, whereas 15 of 16 patients with a large effusion without evidence of tamponade had an interval measuring +0.05 second or less (Fig. 2). Thus, with +0.05 second as the cutoff point, a prolonged MVO-X interval had a sensitivity of 81%, a specificity of 94%, and a predictive value of 89% as an echocardiographic sign of tamponade in this group of patients. Measurement of the MVO-X interval was reproducible, as evidenced by a mean difference between the 2 observers of 0.01 second; a Z value of 2.44 was obtained when the Wilcoxon rank test was applied to the paired observations.

In the 18 patients in whom the volume of pericardial effusion was measured at the time of pericardiocentesis or surgery, a significant correlation was found between the size of the effusion and the MVO-X interval (Fig. 3). Of note is the fact that of the 4 patients with tamponade with an MVO-X interval less than +0.05 second, 3 had an effusion of less than 500 ml.

R-X/R-R interval: The echocardiographic X point occurred after inscription of the electrocardiographic T wave in almost every case. Measurement of the R-X/R-R ratio did not improve separation between the

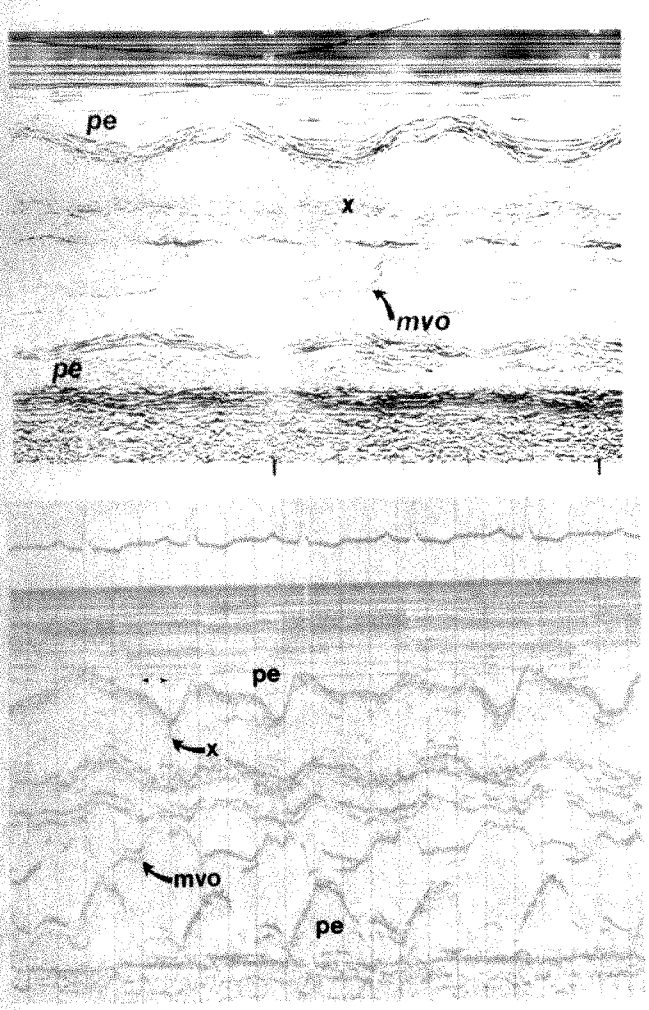

FIGURE 1. Top, simultaneous M-mode recording of right ventricular wall and mitral valve motion from a patient with a large pericardial effusion (pe) without tamponade, demonstrating the time of cessation of posterior motion (x) of right ventricular wall and the time of mitral valve opening (mvo). Paper speed is 100 mm/s. **Bottom,** similar recording from a patient with pericardial effusion and cardiac tamponade. Note the diastolic posterior movement of the right ventricular free wall (prolonged MVO-X interval). Paper speed = 50 mm/s. Time lines (**arrowheads**) = 0.2 second.

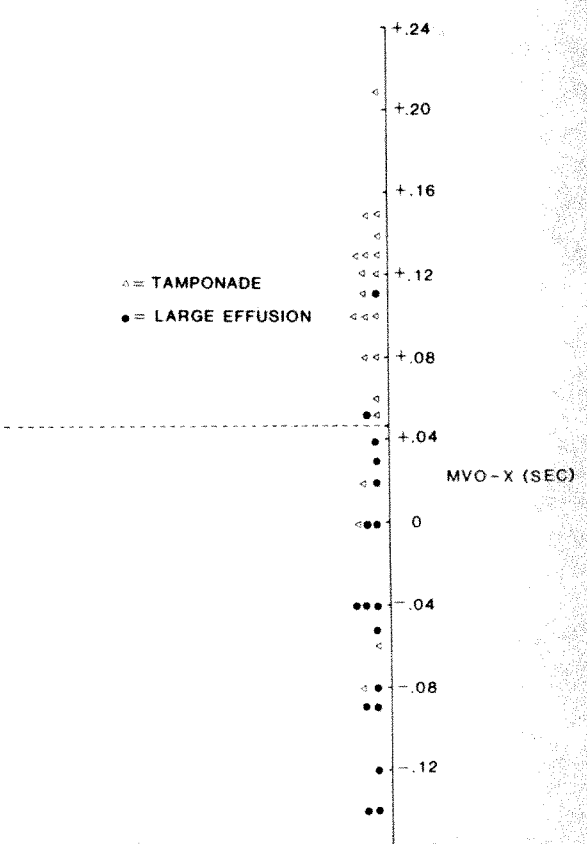

FIGURE 2. Comparison of measurement of MVO-X interval in patients with (**triangles**) and those without (**circles**) cardiac tamponade.

patients with and those without tamponade, as there was considerable overlap between the 2 groups (Fig. 4).

Right ventricular diastolic dimension: No value allowed separation between the groups with and those without tamponade when minimal diastolic dimension of the right ventricle was measured (Fig. 5), although the mean value of the group with tamponade (1.1 cm) was smaller than that of the group without tamponade (1.5 cm).

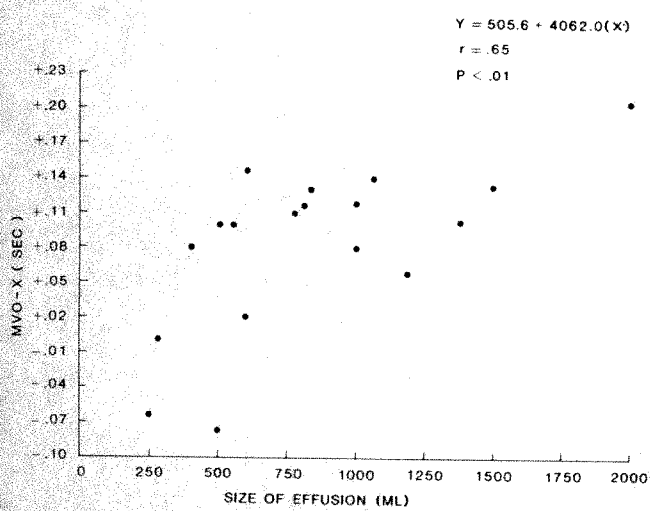

FIGURE 3. Graphic representation of the relation between the volume of pericardial effusion and the MVO-X interval in 18 patients with cardiac tamponade.

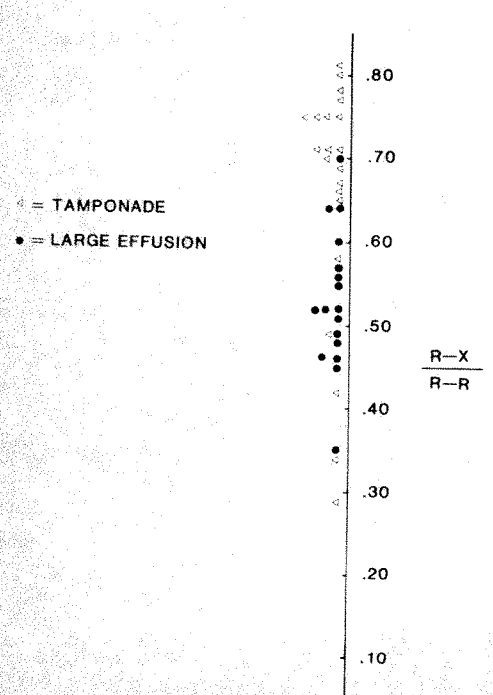

FIGURE 4. Comparison of measurement of R-X/R-R ratio in patients with (**triangles**) and those without (**circles**) cardiac tamponade.

Relief of tamponade: In the 19 patients studied with echocardiography after relief of tamponade, diastolic posterior motion of the right ventricular endocardium was no longer present.

Discussion

Previously described echocardiographic signs of pericardial tamponade: Since the initial description of the identification of pericardial fluid by echocardiography,[4] considerable study has been devoted to the echocardiographic detection of pericardial effusion and its consequences. A noninvasive marker of cardiac tamponade would be of major importance to the clinician, as this complication of pericardial effusion is life-threatening and treatable.

Previous investigators noted a number of findings on echocardiography in patients with cardiac tamponade. Reciprocal respiratory variation in ventricular dimensions was reported,[5,6] but was found to be nonspecific for tamponade because this sign is present in other conditions characterized by greater than normal inspiratory decline in arterial blood pressure.[7,8] An early systolic "notch" on the time-motion recording of the right ventricular wall was described in some patients with cardiac tamponade,[9] but this was not confirmed in a larger series.[10] Expiratory right ventricular compression (right ventricular end-diastolic dimension less than 8 mm) was noted in some studies[11]; however, this abnormality is often noted only in retrospect, that is, after relief of tamponade.

Diastolic posterior right ventricular motion: Preliminary observations[2,3] suggest that posterior motion of the right ventricular wall continues into diastole in patients with tamponade. Martin et al.[12] previously described diastolic "invagination" of the right ventricular wall in 3 patients with a large pericardial effusion studied by 2-dimensional echocardi-

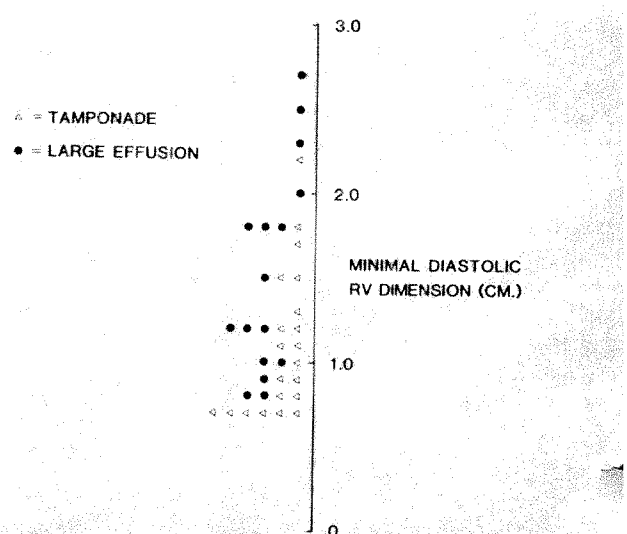

FIGURE 5. Comparison of measurement of minimal right ventricular (RV) diastolic dimension in patients with (**triangles**) and those without (**circles**) cardiac tamponade.

ography. In the present study, we retrospectively examined the M-mode echocardiograms of a large group of patients with pericardial effusion with and without evidence of tamponade with particular emphasis on motion of the right ventricular wall. We found that diastolic posterior right ventricular motion was common in this group of patients. In order to accurately time the cessation of this posterior diastolic motion, it was compared with the motion of the simultaneously recorded mitral valve. We found that persistence of posterior motion of the right ventricular endocardium longer than 0.05 second after mitral valve opening (prolonged MVO-X interval) correlated with the presence of tamponade.

Although none of our patients was studied with 2-dimensional echocardiography, it seems likely that this abnormal motion reflects early diastolic invagination of the collapsible right ventricle. Early diastolic leftward and posterior motion of the interventricular septum has been described in patients with mitral stenosis[13] and was thought to possibly represent left ventricular filling by suction.[14] A similar process may be operative in tamponade[15] and may explain the early diastolic motion abnormality of the right ventricular wall in the present group of patients.

Factors affecting motion of the heart in pericardial effusion: Several factors have been described as affecting the motion of the heart within the pericardial sac when pericardial effusion is present. The volume of the effusion is probably a critical factor. We found a rough correlation between the size of the effusion and the timing of the right ventricular wall motion; the smallest effusions were associated with the shortest MVO-X intervals and with false-negative tests for tamponade by this measure. The size of the effusion and the rapidity of its accumulation influence intrapericardial pressure, which also affects cardiac motion in pericardial effusion. This factor as well as the viscosity of the pericardial fluid may have been operative in the false-negative results in the patient with aortic dissection in this series, who presented with shock and cardiac tamponade. Finally, adhesions may have been present between the visceral and parietal pericardium in some of the patients with more chronic conditions in our series. Such adhesions are not routinely discovered by M-mode echocardiography and may restrain cardiac motion within a larger pericardial effusion.

Clinical implications: No single test detects cardiac tamponade with complete accuracy, and the clinical diagnosis of tamponade may be difficult. Previously described echocardiographic signs of this condition may lack sensitivity and specificity. The finding of persistent diastolic posterior motion of the right ventricular wall is a useful echocardiographic sign of cardiac tamponade when an anterior pericardial effusion is present, particularly because the right ventricular wall is often the easiest cardiac structure to image with ultrasound in patients with larger pericardial effusions. The finding of right ventricular endocardial posterior motion greater than 0.05 second after mitral valve opening adds to the reliability of the echocardiographic diagnosis of cardiac tamponade.

Acknowledgment

We gratefully acknowledge the assistance of David Eppert, who performed many of the echocardiograhic studies, and Rita Caruso, BA, who prepared the manuscript.

Two-Dimensional Echocardiographic Findings In Cardiac Trauma

FLETCHER A. MILLER, Jr., MD, JAMES B. SEWARD, MD, BERNARD J. GERSH, MD, ABDUL J. TAJIK, MD, and PETER MUCHA, Jr., MD

Cardiac contusion is a potentially fatal complication of blunt chest trauma. The diagnosis is obscured because cardiac contusion usually occurs in a setting of multisystem trauma. Furthermore, the electrocardiographic changes are nonspecific. Experience with 2-dimensional echocardiography in evaluating cardiac trauma has not previously been emphasized. This report examines the results of 2-dimensional echocardiographic examinations in 7 patients after significant blunt chest trauma. Generalized right ventricular dilatation was identified in 4 cases; superimposed segmental areas of right ventricular dilatation occurred in 3. Three patients had localized myocardial thinning, and segmental wall motion abnormalities occurred in 2. Additional abnormalities identified included ventricular thrombi (4 right and 1 left ventricular), fibrinous pericardial effusion (1), ruptured tricuspid chordae with flail leaflet (1), and a small aneurysm of the sinus of Valsalva (1). It is concluded that 2-dimensional echocardiography is useful for diagnosing cardiac contusion, for estimating the extent of myocardial damage, and for identifying accompanying cardiac lesions such as thrombi, pericardial effusion, and valvular disruption.

Cardiac contusion is an increasingly recognized entity in patients with nonpenetrating chest injury.[1] The yearly incidence of cardiac trauma in the United States is estimated at 900,000 cases.[2] Although the cardiac lesion may be clinically silent and may be masked by damage to other organs, it can also result in serious or fatal complications.[1-13] In patients with multiple injuries, determination of the severity and extent of associated cardiac trauma may affect management, particularly if operation under general anesthesia is contemplated.

Unfortunately, the diagnosis of cardiac trauma, particularly cardiac contusion, is imprecise and may be confounded by the presence of associated injuries, hypoxia, shock, and metabolic abnormalities. The clinical diagnosis has been based primarily on serial electrocardiographic changes, but these are often nonspecific.[1-5,7,9-12] More recently, creatine kinase isoenzyme determinations[14,15] and radionuclide cardiac scanning[9,13,16-19] have shown promise. Experience with 2-dimensional echocardiography in the evaluation of chest trauma victims has not previously been emphasized. The 7 patients in this report illustrate the value of 2-dimensional echocardiography in assessing cardiac trauma and its sequelae. Two-dimensional echocardiography was helpful in demonstrating wall motion abnormalities, myocardial hematoma, intracavitary thrombus, pericardial effusion, and valvular dysfunction. We believe the direct observations afforded by 2-dimensional echocardiography reflect the nature and extent of cardiac injury and are helpful in the management of these patients.

Address for reprints: Fletcher A. Miller, Jr., MD, Mayo Clinic, Rochester, Minnesota 55905.

Methods

Echocardiography: Two-dimensional echocardiographic examinations were performed with a wide angle, phased-array sector scanner (Varian 3000 or 3400) with a 32 element, 2.25 MHz transducer. When the patient was too ill for transport, examination was performed at the bedside.

Our technique for 2-dimensional examination in acquiring multiple tomographic cardiac sections was previously described.[20] Techniques for imaging and assessing abnormal right and left ventricular segments were also previously described.[21,22] We judged a segment to be abnormal if it was thin, dyskinetic, akinetic, or poorly contractile according to visual

TABLE I Clinical and Laboratory Data in 7 Patients

	Patient						
	1	2	3	4	5	6	7
Age (yr) & sex	27M	20M	41M	22F	50M	16F	21M
Type of accident; associated injuries	Single car, driver; struck chest on steering wheel; soft tissue injuries	Single car, passenger; rib fractures and lacerations	Two-car, driver; struck chest on steering wheel; abrasion over sternum plus multiple lacerations	Single car, driver; pulmonary contusion and fractures of pelvis, scapula, and lumbar spine	Fell 20 feet from roof and struck chest, face, left arm, and leg; multiple fractures of arm and ribs and abrasions	Single car, passenger; pelvic fracture, corneal abrasions, and multiple lacerations	Single car, passenger; dental fracture, closed head injury, and fracture of left femur
Chest symptoms	Sharp, nonpleuritic chest pain, relieved on sitting	Chest pain (in area of rib fractures)	Chest pain, increased with deep breath or movement of left arm	None	None	None	Chest pain consistent with pericarditis; progressive dyspnea on exertion
Cardiovascular examination	Initial: normal; 24 h: loud S_4, triphasic friction rub	Normal	S_4 gallop	Rales in left chest; copious amounts of bright red blood on suctioning	Normal	Normal	New murmurs of aortic insufficiency and tricuspid insufficiency
Electrocardiogram	Day 1: S-T elevation, II, III, aVF, and V_4-V_6 S-T changes normalized by day 10; decreased voltage developed	Day 1: T inversion V_1 and V_2; Day 3: T inversion V_1-V_5; Day 4: frequent VPCs; Day 6: resolving T changes	Day 2: mild sinus bradycardia; serially unchanged	Day 1: T inversion II, III, aVF; T flattened V_5 and V_6; Day 2: normal	Sinus bradycardia (46/min), unchanged from 2 yr earlier; early repolarization II, III, aVF; serially unchanged	Day 4: Slight S-T elevation II, III, aVF; serially unchanged	Incomplete RBBB, vertical QRS axis
Chest X-ray	Day 1: generous heart size and mediastinum, fluid in right chest; increasing cardiomegaly through day 10	Right and left 2nd rib fractures, small right pneumothorax, infiltrate right midlung	Normal	Bilateral pulmonary contusions	Left rib fractures, diaphragmatic hernia	Normal	Cardiomegaly with unusual left heart border

IVC = inferior vena cava; LV = left ventricle; MB isoenzyme = myocardial fraction (value for Patient 1 given after intramuscular injection of analgesic); RA = right atrium; RBBB = right bundle branch block; RV = right ventricle; VPCs = ventricular premature complexes.

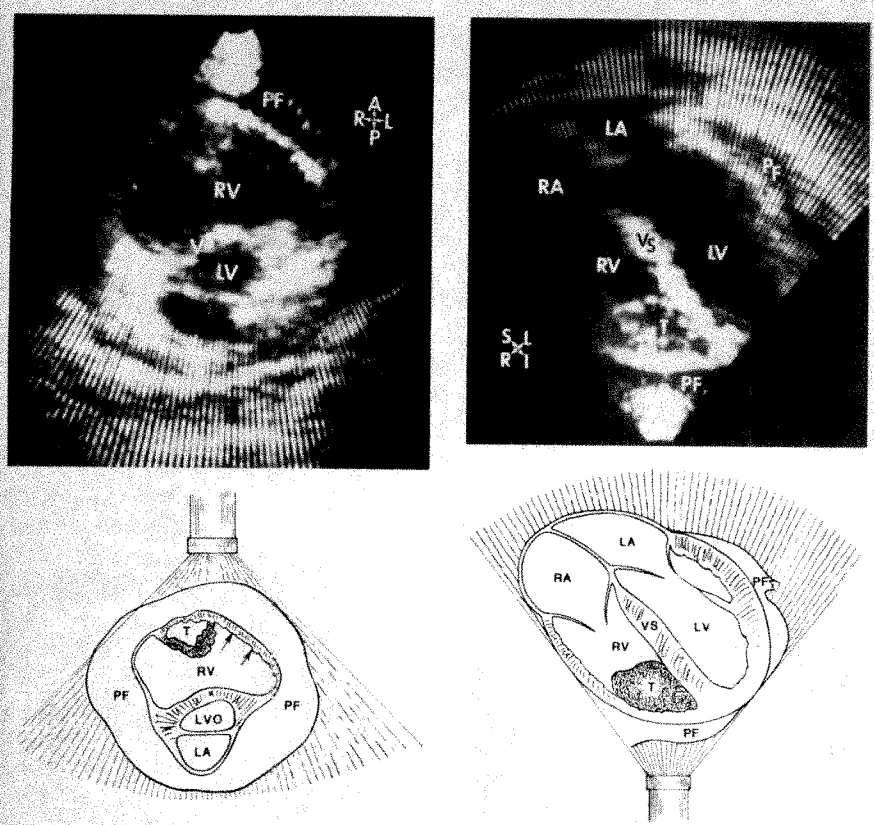

FIGURE 1. Case 1. **Left,** right ventricular contusion. Parasternal short-axis view. The right ventricle (RV) is dilated and the free wall is thinned (**arrows**). In real time the free wall was hypokinetic. Underlying the right ventricular free wall is a mural thrombus (T). Moderate-sized pericardial fluid (PF) accumulation is present. The anterior mitral leaflet separates the normal-sized left ventricular outflow tract (LVO) and the left atrium (LA). **Right,** right ventricular thrombus, 4-chamber view (precordial). The right ventricular thrombus is more clearly visualized in this view. The pericardial fluid is again demonstrated. The left ventricle (LV) is normal. A = anterior; I = inferior; L = left; P = posterior; R = right; RA = right atrium; S = superior; VS = ventricular septum.

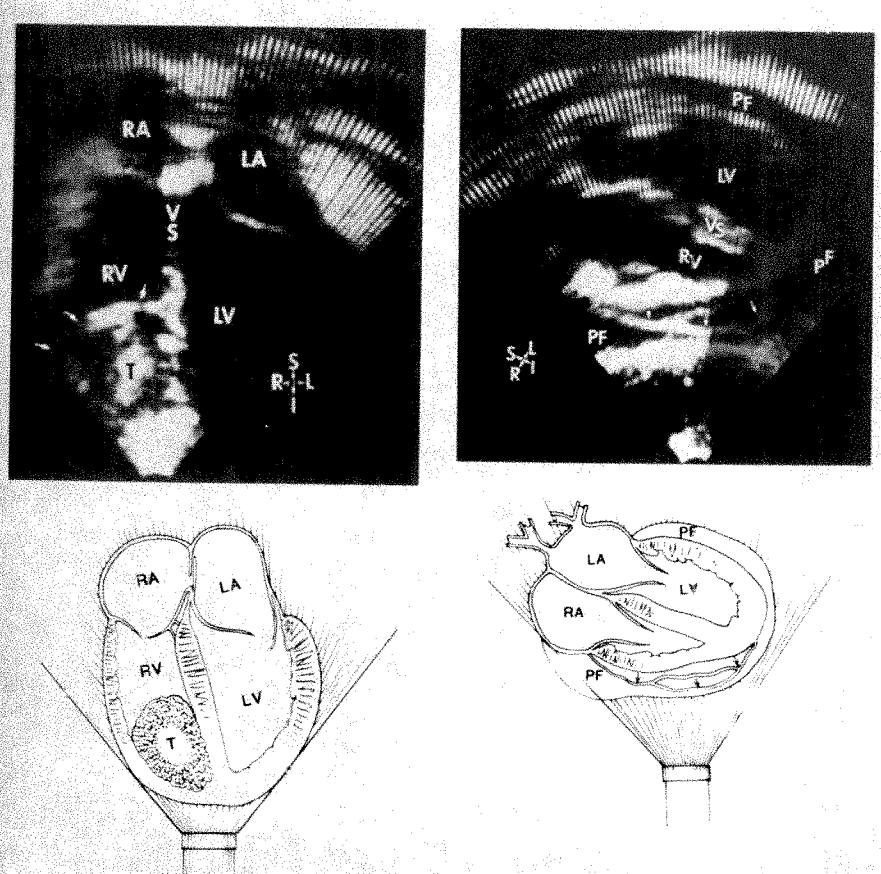

FIGURE 2, left. Case 2. Large right ventricular thrombus. In this apical 4-chamber view, the apex of the right ventricle (RV) is occupied by a large thrombus (T). This thrombus was identified on multiple views and is clearly distinct from the usual right ventricular trabeculations. The left ventricle (LV) is normal. **Arrows** indicate the proximal border of the thrombus. Abbreviations as in Figure 1.

FIGURE 3, right. Case 1. Pericardial effusion with strands. Subcostal 4-chamber view shows that the right ventricle (RV) and left ventricle (LV) are surrounded by a large collection of pericardial fluid (PF). Presumed fibrin strands are visible within the fluid-filled pericardial sac (**arrows**). A right ventricular thrombus was present (see Fig. 1). Abbreviations as in Figure 1.

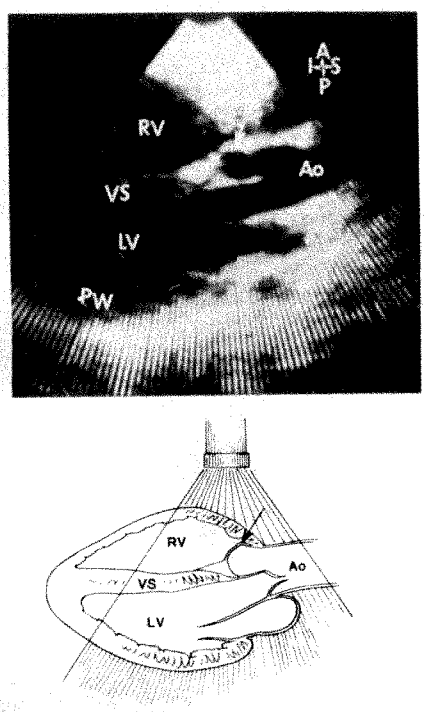

FIGURE 4. Case 7. Aneurysm of the sinus of Valsalva. In a parasternal long-axis view, there is an aneurysm, 1.5 by 1.0 cm, of the right sinus of Valsalva (**arrow**) associated with a new murmur of aortic regurgitation. The right ventricle (RV) appeared normal in this view. Ao = aorta; PW = posterior wall of left ventricle; other abbreviations as in Figure 1.

assessment. Thrombus was diagnosed when a rounded density, contiguous with a ventricular wall, was seen on multiple views.[23] Particular care was taken to distinguish such masses from the right ventricular moderator band and trabeculations. Examinations were recorded on an 0.75-inch videotape for storage and review. Illustrations for this report were obtained by photographing stop-action images from a video screen with a 35 mm camera.

Patient data: Patients' charts were reviewed with respect to the nature of their chest trauma, presenting signs and symptoms, and results of standard examinations, including chest roentgenography, electrocardiography, and cardiac enzyme determinations. Particular attention was paid to the associated cardiac complications and therapeutic interventions.

Injuries in all 7 patients resulted from deceleration accidents. Clinical details are provided in Table I. In 6 patients the initial 2-dimensional echocardiogram was obtained 2 to 7 days after trauma, and follow-up 2-dimensional examinations were performed 1 week to 3 months later. The 7th patient was referred to our institution 11 months after an automobile accident, which resulted in significant disability as a result of tricuspid valve insufficiency.

Results

Clinical findings: Four of the 7 patients had significant chest injuries including rib fracture, chest abrasion, and pulmonary contusion in conjunction with cardiac contusion (Table I). Two of the 3 remaining patients had severe associated trauma at sites distant from the chest. The initial cardiac examination gave abnormal results in only 2 patients: 1 (Case 1) with a pericardial rub and 1 (Case 7) with new murmurs of aortic and tricuspid regurgitation.

TABLE II Summary of 2-Dimensional Echocardiographic Findings

Findings	Patients (n)
Generalized right ventricular dilatation	4
Localized right ventricular dilatation	3
Localized myocardial thinning	3
Segmental wall motion abnormalities	2
Thrombi*	5
Pericardial effusion	1
Valvular rupture	1
Great vessel abnormalities	1

* Four were in the right ventricle; 1 was in the left ventricle.

The cardiac silhouette on the chest roentgenogram was normal in 5 patients and enlarged in 2 patients: the patient with pericardial effusion (Case 1) and the 1 with valvular insufficiency (Case 7). Electrocardiography gave abnormal results in 5 of the 7 patients. In 6 patients the total serum creatine kinase level was elevated at the initial evaluation, and the MB fraction was abnormal in 4. The peak creatine kinase value in 1 patient is unknown. In 2 patients (Cases 3 and 5) the clinical cardiac examination, electrocardiogram, chest roentgenogram, and MB fraction of creatine kinase were within normal limits, and the diagnosis of cardiac contusion was based solely on information supplied by 2-dimensional echocardiography.

Echocardiographic findings (Fig. 1 to 4): Cardiac abnormalities consistent with the diagnosis of cardiac contusion were visualized by 2-dimensional echocardiography in each of these 7 patients (Table I). Echocardiographic abnormalities were identified in the right ventricle in 6 patients and in the left ventricle in 1 (Table II). Four patients had generalized right ventricular enlargement and 3 had localized right ventricular dilatation (Fig. 1). In 3 there was localized myocardial thinning and in 2 hypokinesia of the right ventricular free wall. Intracavitary echo densities compatible with thrombi[23] were visualized in 5 patients (Fig. 1 and 2); 1 of these was in the left ventricle and the remaining 4 were in the right ventricle. The thrombi were usually located on or adjacent to a dilated or abnormally contracting segment of ventricular free wall or apex. A large fibrinous pericardial effusion was identified in 1 patient (Case 1) (Fig. 1 and 3). Echocardiography in Case 7 demonstrated rupture of the anterior tricuspid leaflet chordae, with flail leaflet and features of severe tricuspid regurgitation. Peripheral contrast echocardiography substantiated the presence of severe tricuspid incompetence. In this case an unsuspected aneurysm of the right sinus of Valsalva was also noted on 2-dimensional echocardiography (Fig. 4). Cardiac catheterization was subsequently performed to quantitate the amount of aortic regurgitation, which was found to be mild to moderate. In addition, both severe tricuspid regurgitation and a small sinus of Valsalva aneurysm were confirmed.

There were no deaths in this group of patients. One patient had significant ventricular ectopy which was treated with lidocaine followed by quinidine. Two of the 5 patients with intracavitary thrombi were treated with anticoagulants (Cases 2 and 4). There were no cases of clinically identifiable embolization.

Follow-up 2-dimensional echocardiograms were obtained in 6 of the 7 patients 7 days to 3 months after the initial study. Results of follow-up study were normal in 3 patients, including the 2 patients with intracavitary thrombi who had been treated with anticoagulants. In Case 5 the follow-up study was performed 7 days later, and the right ventricular dilatation and thrombus were unchanged. In Case 1 a follow-up study at 6 weeks showed resolution of the fibrinous pericardial effusion and shrinkage and increased echo-density of the right ventricular thrombus. Shrinkage and increased echo-density of the thrombus were also noted on the 30 day follow-up study in Case 3.

Discussion

Cardiac contusion in chest trauma: Clinically recognizable cardiac contusion occurs in 9 to 21% of patients with significant blunt chest trauma.[1,2,12,13] Cardiac contusion may be the most common unsuspected visceral injury leading to sudden death after chest trauma.[1] Life-threatening arrhythmias have been well recognized in both clinical and experimental contusions.[1–4,7,9–11,13,24] Other potentially fatal complications include conduction disturbances,[1–4,7] hemopericardium with tamponade,[1–4,7,10,11,13] cardiac rupture,[2–5,7,12,13] congestive heart failure,[2–5,10] and thromboembolic events.[2–6,10] Chronic cardiac disability resulting from valvular rupture,[2–4,9,10] ventricular-septal rupture,[2–4,7,9,11–13] ventricular aneurysm,[2–4,11,13] and constrictive pericarditis[2–4,8,10,13,25] have also been reported. Clearly, it is important to recognize complicating cardiac injury in patients with chest trauma.

Clinical diagnosis: Until recently the clinical diagnosis of cardiac contusion was based on a history of significant chest trauma accompanied by serial electrocardiographic changes.[1,2,4,7,9–12] The latter consist of the entire spectrum of changes typically seen after myocardial infarction, but often they are nonspecific.[26] There may be a delay in the evolution of electrocardiographic changes ranging from several hours to days after the chest trauma. These changes usually resolve more quickly than those associated with ischemic myocardial infarction. More recently, creatine kinase isoenzyme analysis has been used in the diagnosis of cardiac contusion.[14,15] The myocardial fraction reaches its peak 6 to 24 hours after trauma and returns to normal levels at 24 to 72 hours. Technetium pyrophosphate radionuclide (hot-spot) imaging has also been used to assess possible myocardial damage in trauma cases.[9,13,16–19] In cases of extensive soft tissue and skeletal damage associated with cardiac contusions, isotope imaging with pyrophosphate may not be sufficiently discriminating, particularly when there is right ventricular involvement and isotope activity is in close proximity to interfering uptake in the sternum.

Echocardiographic diagnosis: Coleman et al.[19] reported on the potential use of echocardiography in experimental left ventricular contusions. Their study utilized the M-mode echocardiographic technique, and they acknowledged the technical difficulty of obtaining satisfactory echocardiograms in the dog model. No consistent echocardiographic abnormalities were seen. Motro et al.[27] recently reported a single case of right ventricular contusion, with aneurysm formation diagnosed by 2-dimensional echocardiography and radionuclide angiography.

Our cases illustrate the potential value of 2-dimensional echocardiography in assessing cardiac contusion. As opposed to clinical, electrocardiographic, and enzyme determinations, 2-dimensional echocardiography provides a means for direct visualization of cardiac structures and chambers. Wall motion abnormalities and chamber dilatation and wall thinning permit a gross estimate of the extent of myocardial damage. Two-dimensional echocardiography allows discrimination of right from left ventricular contusion and right ventricular contusion from traumatic pericardial effusion with tamponade. The location of the right ventricle and its proximity to the anterior chest wall and sternum increase its vulnerability during chest trauma. From an electrocardiologic viewpoint, depolarization of the right ventricle is overshadowed by events in the ventricular septum and thicker-walled left ventricle.[28] Therefore, the electrocardiogram with the use of conventional leads may be an insensitive method of diagnosing right ventricular necrosis.[29,30] Attention is also drawn to the hemodynamic similarity between pericardial disease and right ventricular infarction.[31,32] This similarity applies to other conditions in which right ventricular compliance is reduced, as in patients with restrictive cardiomyopathy,[33] and it presumably also applies to right ventricular contusion. In blunt chest trauma, the echocardiographic differentiation between right ventricular contusion and pericardial effusion with cardiac restriction may be crucial to patient management. Similarly, the echocardiographic differentiation between right and left ventricular contusion appears important in making therapeutic decisions similar to those in the patient with ischemic right ventricular infarction.[31,32,34]

In the present series the finding of intraventricular filling defects, characteristic of thrombi, is of particular interest. No patient in this series had clinical evidence of systemic or pulmonary emboli. There is a single case report[6] of death secondary to pulmonary embolism 1 month after cardiac contusion, with autopsy proof of right ventricular mural thrombosis. Whether anticoagulation should be routine in cases of cardiac contusion, provided such therapy is not contraindicated by associated injuries or complications, is currently a debated and unresolved issue.[2,5,6,10,13] Whether these patients with thrombi identified by 2-dimensional echocardiography require anticoagulation cannot be answered definitively from our data. In the 2 cases in which anticoagulants were used, thrombi were not noted on follow-up examination (at 6 days and at 3 months);

in the 3 cases in which anticoagulants were not used, thrombi persisted on follow-up examinations performed 7 days to 10 weeks after the initial study.

Diagnostic implications: Accurate diagnosis of cardiac contusion is challenging because this injury usually occurs in a milieu of multisystem trauma. Two-dimensional echocardiography provides the physician with a useful, noninvasive tool for assessing trauma patients for possible cardiac contusion. It supplements the electrocardiogram and cardiac enzyme determinations in making this diagnosis by providing direct visualization of structural and motion abnormalities consistent with cardiac contusion. It also allows localization of the injury, gross estimation of the amount of myocardium involved, and documentation of complications, including mural thrombi, valvular rupture, and pericardial effusion. Data regarding the sensitivity and specificity of 2-dimensional echocardiography in the diagnosis of cardiac contusion and in predicting serious events such as tamponade, systemic or pulmonary emboli, aneurysm, cardiac wall or valve rupture, or ventricular arrhythmia await a larger prospective study.

Assessment of Left Ventricular Relaxation in Patients With Valvular Regurgitation

MICHEL F. ROUSSEAU, MD, HUBERT POULEUR, MD, ANDRÉ A. CHARLIER, MD, and LUCIEN A. BRASSEUR, MD

Impaired left ventricular (LV) relaxation has been demonstrated in patients with coronary heart disease and in patients with hypertrophic or congestive cardiomyopathy but not yet in those with aortic or mitral regurgitation. Indeed, in patients with valvular regurgitation the lack of isovolumic relaxation and variations in the filling rate invalidate most relaxation indexes. The aim of this study was to assess ventricular relaxation in patients with valvular insufficiency. The hemodynamic and angiographic data were analyzed during the phase of decreasing left ventricular elastance (that is, when pressure is decreasing while volume is increasing) in 57 patients (27 with valvular regurgitation, 17 normal subjects, and 13 patients with coronary heart disease). Starting from a fixed level of wall stress (40 kdyne/cm^2), we determined the incremental LV elastance (ratio $\Delta P/\Delta V$) and the changes in velocity of lengthening produced by a constant increase in LV volume (+20 ml/m^2). In aortic and mitral regurgitation, both the incremental elastance (−0.52 versus −0.95 mm Hg/ml per m^2 in normal subjects: $p < 0.001$) and the changes in velocity of lengthening (+0.76 versus +1.17 circ/s; $p < 0.05$) were abnormal. These indexes were also impaired in patients with coronary heart disease. Further, significant correlations were found in the whole group between incremental elastance and ejection fraction ($r = 0.63$), mean velocity of fiber shortening ($r = 0.62$), and end-systolic volume ($r = 0.53$), suggesting a relation between impaired incremental elastance and alterations in inotropic state or afterload, or both. This hypothesis was confirmed by the fact that patients who had a peak systolic wall stress of less than 400 kdyne/cm^2 and a normal index of inotropic state also had normal incremental elastance: in contrast, all but 1 patient with the same afterload but abnormal contractility had abnormal incremental elastance. It is concluded that abnormalities in early diastolic filling are common in patients with valvular regurgitation and are likely to be related to impaired LV relaxation.

Myocardial relaxation, the active process by which ventricular muscle returns to its initial length and tension,[1] has been extensively studied in isolated muscle[1-6] and in animal experiments.[7-11] In man, LV relaxation has been assessed using indexes such as the time course of isovolumic pressure decrease or the rate of changes in left ventricular volume or dimension during the rapid filling phase.[12-22] These approaches have provided clear evidence that LV relaxation is impaired in patients with coronary heart disease, particularly those with hypertrophic or congestive cardiomyopathy.[12-22] It has also been suggested that clinical manifestations of LV failure might partly result from such alterations in the relaxation process of the left ventricular and that several therapeutic interventions might improve this impaired process and the patient's functional symptoms.[17,18,22-24]

Despite the clinical relevance of relaxation abnormalities, it has not yet been established whether or not LV relaxation could be impaired in patients with valvular regurgitation. In patients with aortic or mitral regurgitation, the lack of isovolumic relaxation and the wide variations in filling rate invalidate classic indexes of relaxation. The aim of the present study was therefore to develop a method, based on ventricular elast-

ance, to assess LV relaxation in the absence of isovolumic relaxation.

Methods

Study patients: Fifty-seven patients (42 men and 15 women) were included in this study. All had sinus rhythm; cardiac catheterization was performed for diagnostic purposes. Of these patients, 17 (mean age 49.6 years, range 28 to 59) who had atypical chest pain but a completely normal ventriculogram and coronary arteries were considered normal control subjects. Twenty-seven patients (mean age 44.6 years, range 22 to 69) had valve disease: 13 had mitral regurgitation, 10 had aortic regurgitation, and 4 had combined mitral and aortic regurgitation. No patient in this group had associated valvular stenosis or coronary heart disease. Mitral regurgitation resulted from mitral valve prolapse in only 2 patients and none resulted from cardiomyopathy. Thirteen other patients (mean age 48.7 years, range 37 to 61) had coronary heart disease and previous myocardial infarction.

All cardioactive drugs were discontinued at least 48 hours before the catheterization procedure, and in most cases the delay was 6 to 7 days. Informed consent was obtained from each patient, and no complication occurred as a result of this study.

Study protocol: Left heart catheterization was performed through the femoral approach with the patient in the fasting state and without premedication.[16,19] High fidelity left ventricular pressures were recorded at low (0 to 160 mm Hg) and high (0 to 40 mm Hg) gains with a 5 or 6Fr micromanometer-tip catheter (Millar Instruments). The micromanometer system was calibrated against a mercury manometer before insertion and again after withdrawal. Aortic pressure was measured through an 8Fr pigtail fluid-filled catheter connected to a Statham P23 ID strain gauge.

Left ventriculography was performed utilizing single plane 35 mm cineangiography at 50 frames/s in the right anterior oblique projection (Philips Poly-Diagnost C). The hemodynamic variables and a cine frame marker were recorded on a multichannel recording system at a paper speed of 200 mm/s (Honeywell 1858) and on magnetic tape (Honeywell 101). LV pressure during ventriculography and the time of the peak of the R wave were also sampled synchronously with frame exposure and displayed on the corresponding cine frame in digital form (Cine Data Philips).

In 8 patients with valvular disease (3 aortic, 4 mitral, and 1 combined aortic and mitral regurgitation) 20 mg of nifedipine was administered sublingually 5 minutes after the first ventriculogram was taken. A second ventriculogram was obtained 20 minutes after administration of nifedipine.

Measurements and computations: For evaluation of left ventricular function, cine films were projected to a video camera and ventricular silhouettes were outlined with a light pen on a video screen. Both premature and postpremature beats were excluded from analysis. A computer system (LVV Philips 100) derived the correction factor for X-ray magnification and calculated volumes every 20 ms applying Simpson's rule.[25]

Wall thickness at the LV equator was traced on the last diastolic frame and was computed for the subsequent frames assuming a constant LV mass.

Mid-wall circumferential stress was calculated using the formula of Sandler and Dodge[25]: Stress = $(Pb/H)\{1 - b^3/[a^2(2{\cdot}b + H)]\}$ kdyne/cm^2, where P = left ventricular pressure, H = wall thickness, a = mid-wall semimajor axis, and b = mid-wall semiminor axis.

The ejection fraction and mean velocity of fiber shortening or lengthening were calculated according to the standard formula.[26,27] Volume data were corrected for the body surface area and end-systolic or end-diastolic volumes were defined, respectively, as the smallest and largest LV volumes obtained.

Ventricular elastance: To assess LV properties during relaxation, we analyzed angiographic and hemodynamic data during the period of decreasing ventricular elastance (that is, when LV pressure was decreasing or remaining constant despite an increase in ventricular volume). Accordingly, during this period the rate of tension reduction within the ventricular walls was a primary determinant of the ventricular elastance (which was equal to the pressure/volume ratio). To evaluate ventricular elastance during this phase of diastolic filling, we computed incremental elastance (Δpressure/Δvolume) which, in contrast to the pressure/volume ratio, was not affected by absolute values of ventricular volume. In addition, to allow comparison from patient to patient despite the variations in filling rate and in ventricular size, and because ventricular elastance is continuously changing during diastole (Fig. 1), the procedure to compute incremental elastance was standardized (Fig. 2). In each patient the ratio Δpressure/Δvolume was determined starting at a common level of LV wall stress (≈40 kdyne/cm^2) and the increment in volume (ΔV) was constant approximately (20 ml/m^2). This standardized incremental left ventricular elastance (ΔP/ΔV, mm Hg/ml per m^2) was used as the first index of the diastolic properties during relaxation. The changes in velocity of fiber lengthening (Δ velocity of lengthening) attending the standard increase in ventricular volume were also computed and used as a second index of relaxation.

Index of inotropic state: Because the isovolumic and ejection phase indexes of inotropic state are of little value in patients with valve disease,[28] the slope of the linear relation between LV wall stress and volume during the late ejection was used as an index of the inotropic state. This slope was computed in 47 patients, as previously described.[29,30] Briefly, an algorithm first detected the end of systole (defined as the frame with the maximal pressure/volume ratio); starting from this frame and going backwards throughout ejection, and the stress-volume data were then fitted to linear relations using least-squares regression techniques. In each patient, the slope of the relation with the highest correlation coefficient (r, ranging from 0.95 to 0.99) and with at least 5 data points was selected to characterize the inotropic state. Previous studies in man and in dogs have shown that this index was sensitive to changes in inotropic state, but in contrast to classic ejection phase indexes it was insignificantly affected by changes in preload or afterload.[30]

Statistics: Statistical comparisons among the groups were performed with a Mann-Whitney test,[31] whereas the correlations among the different indexes of systolic and diastolic function were determined using linear least-squares regression analysis. The paired data before and after nifedipine were compared with use of a paired t test.

Results

Systolic and diastolic function under basal conditions: Table I summarizes relevant indexes of ventricular function in the 3 groups. Patients with valve disease had significant increases in LV end-diastolic pressure (17.5 ± 7.8 versus 11.0 ± 4.0 mm Hg in normal subjects; $p < 0.01$), end-diastolic volume (178 ± 48 versus 93 ± 18 ml/m^2; $p < 0.01$), and end-systolic volume (58 ± 27 versus 27 ± 9 ml/m^2; $p < 0.01$) as well as in LV

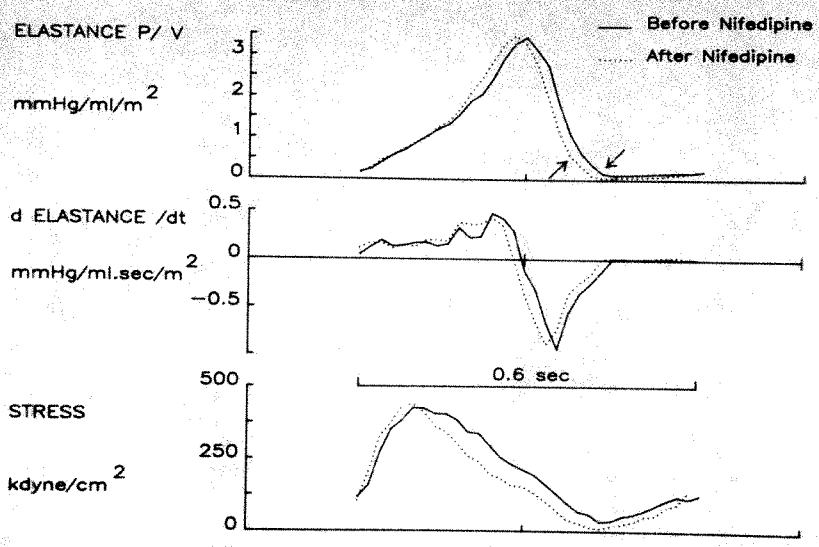

FIGURE 1. Evolution of ventricular elastance (P/V), its first derivative (d ELASTANCE/dt) and wall stress in a patient with severe aortic regurgitation, before and after administration of nifedipine. **Arrows** indicate values of ventricular elastance at a wall stress of 40 kdyne/cm^2. At this wall stress, ventricular elastance is still decreasing in both cases, as confirmed by the negative value of d Elastance/dt. After nifedipine, both mean systolic and mean diastolic wall stress were reduced and the decline in ventricular elastance occurred earlier. The end-diastolic volumes before and after nifedipine were, respectively, 132 and 138 ml/m^2, and the end-systolic volumes were 32 and 28 ml/m^2.

mass. Ejection fraction (68 ± 9%) and mean velocity of fiber shortening (1.30 ± 0.42 circ/s) were not significantly different from normal values. The slope of the late stress-volume relation, computed in 21 patients, was reduced below the lowest normal value of 3 kdyne/cm^5 per m^2 in 12 patients; this index remained within normal limits (range 3 to 9.3 kdyne/cm^5 per m^2) in 9 other patients.

The patients with coronary heart disease and previous myocardial infarction also had significant increases in end-diastolic (+ 35%; p <0.01) and end-systolic volumes (+122%; p <0.01). Ejection fraction (56 ± 9%) and mean velocity of fiber shortening (1.04 ± 0.35 circ/s) were reduced, and the peak systolic wall stress was increased by an average of 17% (p <0.05). The slope of the stress-volume relation was computed in 11 patients, only 3 of whom had a value below the lowest normal limit of 3 kdyne/cm^5 per m^2.

Table II summarizes the proposed indexes of LV relaxation during the early filling phase. Both incremental elastance (−0.52 ± 0.43 versus −0.95 ± 0.48 mm Hg/ml per m^2; p <0.01) and the changes in velocity of lengthening were significantly different from normal in patients with valvular regurgitation. Similar alter-

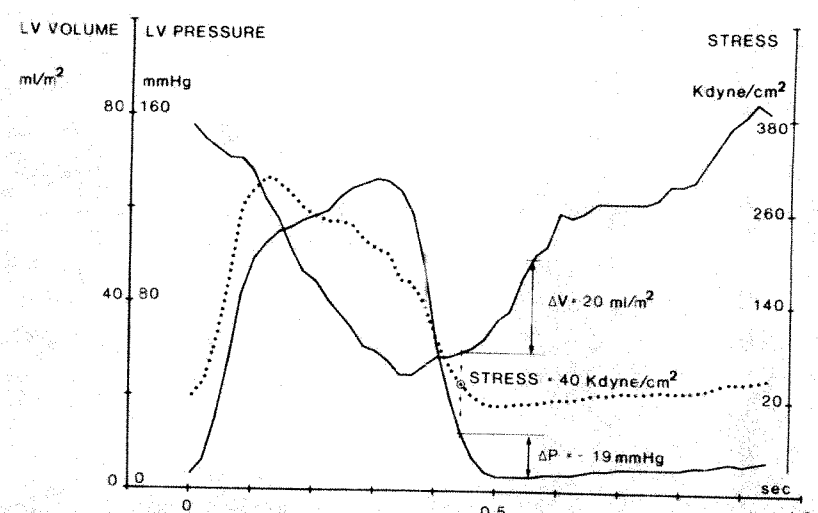

FIGURE 2. Method used to assess the LV incremental elastance ($\Delta P/\Delta V$) during ventricular relaxation. The LV pressure, volume, and wall stress of a normal subject are plotted against time. The LV pressure and volume data corresponding to a wall stress of 40 kdyne/cm^2 are first determined; then the changes in LV pressure (ΔP) attending a standard increase in volume (ΔV + 20 ml/m^2) is determined and the incremental elastance (in this case −19/20 = −0.95 mm Hg/ml per m^2) is calculated.

ations in both indexes were observed in those with coronary heart disease. LV pressure decreased in all groups during this phase, but despite identical increases in ventricular volume this pressure decrease was greater in normal subjects than in patients with heart disease. However, the range of normal values in incremental elastance was large, as was the overlap among groups (Fig. 3). The data were examined to determine the rationale for these findings.

Relations among left ventricular incremental elastance, ejection phase indexes, and peak systolic wall stress: No correlation was found between incremental elastance and age, functional class, cause of valvulopathy, grade of regurgitation, heart rate, end-diastolic pressure or volume, or left ventricular mass. However, some correlations were evident in all groups between incremental elastance and ejection fraction, mean velocity of fiber shortening, and end-systolic volume index (r = 0.63, 0.62, and 0.53, respectively; n = 57; $p < 0.001$).

Because relaxation, like ejection phase indexes, is influenced by changes in afterload, this influence was analyzed using peak systolic wall stress as an index of afterload.[32,33] This approach first indicated that the normal subjects with a peak systolic wall stress of less than 400 kdyne/cm^2 had a more negative incremental elastance than the normal subjects with a higher peak systolic wall stress (−1.07 ± 0.51 versus −0.73 ± 0.34 mm Hg/ml per m^2; $p < 0.05$). Similar trends were observed in patients with heart disease (−0.78 ± 0.40 versus −0.37 ± 0.33 mm Hg/ml per m^2; $p < 0.05$) and in patients with valve disease (−0.62 ± 0.43 versus −0.27 ± 0.32; $p < 0.025$), indicating that peak systolic wall stress had to be considered in order to correctly interpret the value of incremental elastance. However, several differences between normal subjects and patients with valvular regurgitation persisted even when the influence of the afterload was taken into account (Fig. 4). Indeed, 14 of the 27 patients with valve disease still fell outside the normal range of incremental elastance.

Relations between the slope of the late systolic stress-volume relation and LV incremental elastance: To assess the influence of inotropic state on incremental elastance, the patients were classified in 2 groups: those with a normal slope (3 to 9.3 kdyne/cm^5 per m^2) and those with a depressed slope (Fig. 5). All patients with valve disease with a low peak systolic wall stress (400 kdyne/cm^2 or less) and a normal slope fell within the normal range of incremental elastance. In

* $p < 0.05$, † $p < 0.01$.
All values are mean ± SD. Starting stress, starting volume, see Methods for explanation; Δ volume, Δ pressure = changes in LV volume and pressure used to calculate incremental elastance; Δ stress and Δ velocity of lengthening = changes in LV wall stress and in velocity of wall lengthening during the period when incremental elastance is computed.

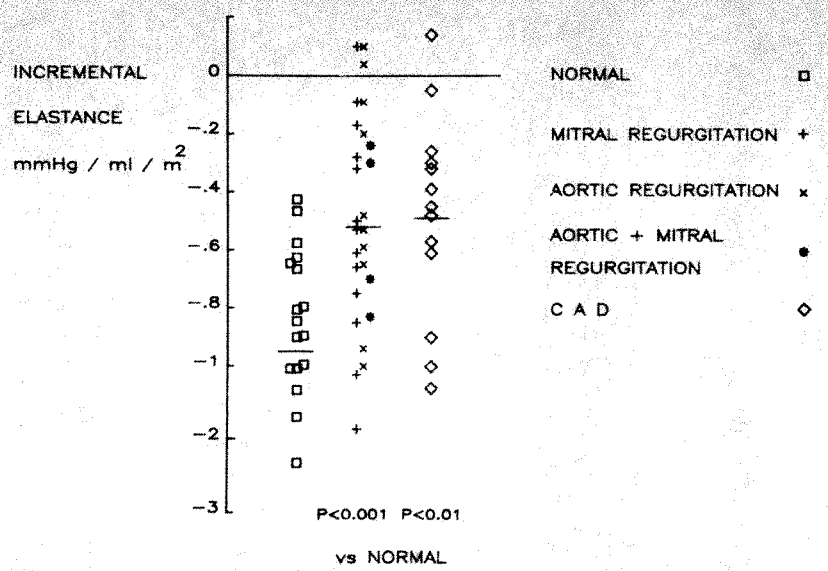

FIGURE 3. Individual values of incremental elastance in normal subjects, in patients with valvular regurgitation, and in patients with coronary heart disease (CAD). The scale of incremental elastance has been magnified between 0 and −1.

contrast, incremental elastance in all but 1 patient with valve disease with similar afterload but a depressed slope was abnormal ($p < 0.001$). When we compared patients with valve disease with a normal slope with those with an abnormal slope and impaired incremental elastance, the latter group also had significantly higher LV end-diastolic pressure (19.9 ± 8.8 versus 11.4 ± 1.9 mm Hg; $p < 0.01$), end-diastolic volume (194 ± 42 versus 141 ± 27 ml/m^2; $p < 0.01$), and end-systolic volume (62 ± 22 versus 32 ± 9 ml/m^2; $p < 0.01$). The mean velocity of fiber shortening was also reduced in this subgroup (1.23 ± 0.15 versus 1.77 ± 0.22 circ/s; $p < 0.01$) despite identical values of peak systolic wall stress. The trend was similar at a higher level of peak systolic wall stress, but the number of patients was too small for statistical comparisons (average incremental elastance in 6 normal subjects: −0.73; in 2 patients with valve disease with a normal slope: −0.47; and in 3 patients with valve disease with an abnormal slope: −0.23).

Effects of nifedipine on LV systolic and diastolic function in patients with valvular regurgitation: Table III summarizes the hemodynamic changes in-

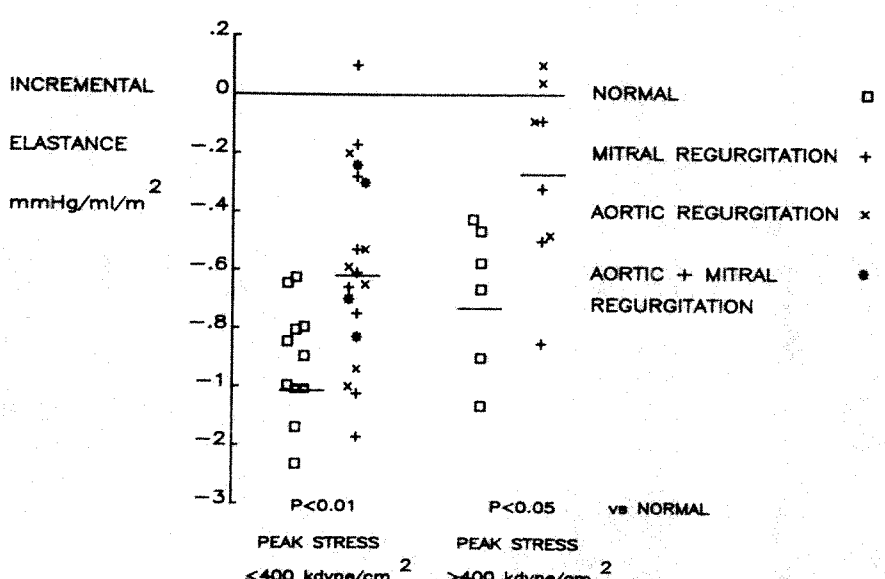

FIGURE 4. Individual values of incremental elastance in normal subjects and in patients with valvular regurgitation separated according to their value of peak systolic wall stress. Although there is a significant trend toward an increase incremental elastance with an increasing wall stress, the groups with valve disease remained significantly different from the normal group. The scale of incremental elastance has been magnified between 0 and −1.

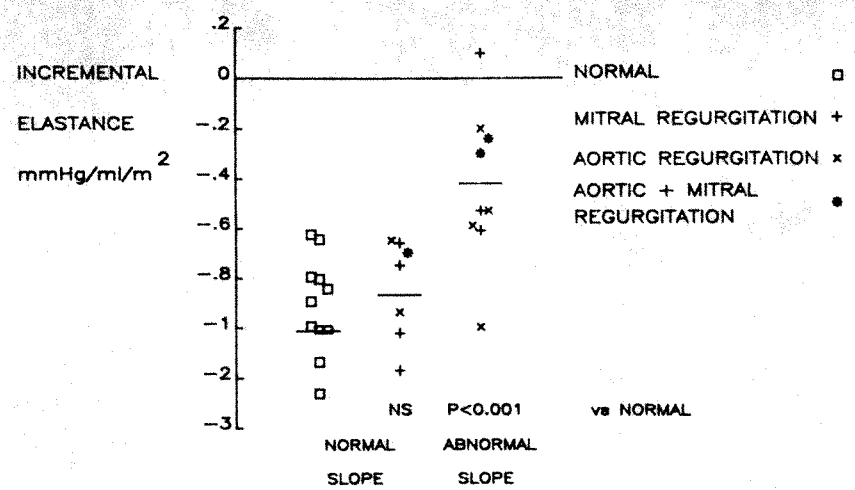

FIGURE 5. Individual values of incremental elastance in normal subjects and in patients with valve disease with similar afterload (peak systolic wall stress less than 400 kdyne/cm^2). Only the patients with valve disease and an abnormal index of inotropic state (abnormal slope: see Methods) had impaired incremental elastance. The scale of incremental elastance has been magnified between 0 and −1.

duced 20 minutes after 20 mg of nifedipine was administered sublingually to 8 patients. The late systolic slope was not significantly affected by nifedipine (−11%; difference not significant), but left ventricular systolic pressure decreased in all patients from 145 ± 27 to 125 ± 25 mm Hg ($p < 0.01$), and peak systolic wall stress was reduced in all but 1 patient. Simultaneously, small increases in ejection fraction and in mean velocity of fiber shortening and significant improvement in incremental elastance were noted. The velocity of fiber lengthening also tended to be greater, but this increase did not reach statistical significance.

Discussion

Our data indicate that an index of LV elastance determined during early diastolic filling is abnormal in many patients with valvular regurgitation or coronary heart disease. Interpretation of these observations requires consideration of several points.

Problems in assessing ventricular relaxation in valvular regurgitation: Classic indexes of LV relaxation are not valid in the absence of an isovolumic phase. Under such circumstances, indexes derived from the rate of pressure decrease such as peak−dP/dt[12] or the time constant of isovolumic pressure decrease[7–10,13,15,16,19] no longer reflect the rate of tension decrease within the myocardium but rather reflect a complex interplay between the amount of regurgitation and myocardial relaxation. Similarly, indexes based on the peak filling rate[18,20–22] or on filling fractions[20] are likely to be greatly influenced by the rapid volume overload. These problems probably explain why left ventricular relaxation has received little attention in patients with valvular regurgitation.

Under experimental conditions, when static pressure-volume or stress-strain relations are readily obtained,[34,35] it is easy to quantify the influence of relaxation during diastole even in the presence of a valve leak. However, this method is difficult to apply in patients with valve disease because hemodynamic interventions and repeated ventriculograms are required to obtain a sufficient range of static pressure-volume data. To solve these problems, it was therefore necessary to develop an index of diastolic properties, directly related to the relaxation rate and applicable both in normal patients and in patients with heart disease. It was necessary to focus the analysis on the early diastolic filling phase because during this period the relaxation rate is a pri-

TABLE III Effects of Nifedipine on Left Ventricular Systolic and Diastolic Function in Patients With Valvular Regurgitation

	Heart Rate (beats/min)	LVEDP (mm Hg)	EDVI (ml/m^2)	ESVI (ml/m^2)	EF (%)	Mean VCF (circ/s)	Peak Systolic Wall Stress (kdyne/cm^2)	Slope (kdyne/cm^5 per m^2)	Incremental Elastance (mm Hg/ml per m^2)	Δ Velocity of Lengthening (circ/s)
Control subjects (n = 8)	81 ± 20	22.6 ± 11.2	188 ± 52	56 ± 25	71 ± 6	1.38 ± 0.38	363 ± 67	2.88 ± 1.73	−0.52 ± 0.30	0.82 ± 1.17
20 minutes after nifedipine (n = 8)	88 ± 12	22.0 ± 12.2	191 ± 46	52 ± 21	74 ± 5*	1.59 ± 0.39†	320 ± 69*	2.58 ± 1.46	−0.91 ± 0.44†	1.36 ± 1.91

mary determinant of ventricular elastance, as indicated by the fact that LV pressure is decreasing despite an increase in LV volume.

To allow meaningful comparisons from patient to patient despite the wide variations in ventricular volume and wall thickness, it appeared useful to analyze this phase starting at an identical level of wall stress rather than starting at an identical level of pressure or wall strain. Indeed, computations of strain require exact knowledge of the ventricular dimension at zero wall stress, a datum unavailable in patients. The selected procedure ensured that a common level of residual systolic wall tension was present in all patients studied; nevertheless, despite large changes in ventricular size, this common level generally occurred at comparable ventricular pressure in normal subjects and in those with valve disease. This finding suggests that in many patients the increased wall thickness largely compensated for the deleterious effects of cardiac dilatation. Empirically, we found that a value around 40 kdyne/cm^2 (range 30 to 50) was appropriate because it was present in all patients during this phase. Starting from the pressure and volume data producing a stress of about 40 kdyne/cm^2, the incremental LV elastance was then computed using a standard increase in volume (20 ml/m^2).

Incremental elastance was preferred to the absolute value of elastance (pressure/volume [P/V]) or to the first derivative of elastance (d[P/V]/dt) (Fig. 1) because the values of incremental elastance ($\Delta P/\Delta V$) are not influenced by absolute ventricular volume. In contrast, both elastance and its first derivative greatly depend on the ventricular geometry at which they are determined and are abnormal in all patients with an enlarged heart, regardless of myocardial function. Because this index was new, we decided to determine whether it was sensitive enough to show the abnormalities in ventricular relaxation often present in patients with coronary heart disease.[12,15,16,19–21] Table II indicates that both indexes were abnormal in this group. Furthermore, the patients with coronary heart disease and abnormal incremental elastance also had an abnormal time constant of isovolumic pressure decrease[16,19] and an abnormal first-third filling fraction.[20]

Several problems arise when computing (as in the present study) the incremental elastance directly from the raw angiographic data without any interpolation between frames. This method does not always provide a frame with the starting stress required. Consequently, some variations in starting stress and volume increments (Table II) were unavoidable, and this certainly contributed to some extent to the variations in the calculated elastance as well as in the calculated changes in velocity of lengthening. The use of a filtering process allowing interpolations between frames certainly could improve the precision of the computed indexes. Finally, because a 20 ml/m^2 volume increment was arbitrary, the values of incremental elastance derived from a 10 ml/m^2 volume change were also studied. Similar conclusions could be drawn from this index. In addition, it even appeared more sensitive: The average incremental elastance with use of a ΔV = 10 ml/m^2 was −1.96 mm Hg/ml per m^2 in normal subjects and −0.79 in patients with valve disease ($p < 0.01$). The changes in wall stress (−25 versus −12 kdyne/cm^2; $p < 0.01$) and in velocity of lengthening (+1.94 versus +0.26 circ/s; $p < 0.01$) during this period also differed between the 2 groups. However, the value of this other index could not be obtained in more than 30% of the patients because the changes in ventricular volume between angiographic frames exceeded 10 ml/m^2 during this period of decreasing elastance. Accordingly, a volume increment of at least 20 ml/m^2 was preferred, but the use of angiographic techniques with a higher frequency response should probably provide a better estimation of the ventricular elastance.

Significance of the changes in incremental elastance and velocity of lengthening during the early diastolic filling phase: Among the different factors determining the diastolic properties of the left ventricle,[24,36] 4 should be considered in interpreting our observations: the passive elasticity,[36] the active relaxation process,[8,13,17,18,23,24] the viscous properties,[34,35,37,38] and finally, the restoring forces[39] that represent the elastic recoil of the myocardium. In our study the influence of the passive elastic properties is probably negligable, as indicated by the fact that both LV pressure and wall stress were decreasing during the increase in ventricular volume.

In contrast, the relaxation process is likely to play a major role during this diastolic phase, and several arguments favor the hypothesis that the changes in both indexes observed in the present study indeed reflect an impaired ventricular relaxation. However, it is well known that relaxation is a load-dependent phenomenon,[6,7,10,11] and we observed some correlations between an increased afterload and the values of incremental elastance. A slower relaxation caused by a greater afterload of the myocardium might therefore partly explain the variations in incremental elastance observed between normal subjects and patients with valve disease (Fig. 4). However, changes in inotropic state also greatly modify myocardial relaxation,[2,6–8,11,19] a decrease in inotropic state being generally attended by a slower relaxation. Patients with valve disease and a normal index of myocardial contractility generally had a normal incremental elastance, whereas those with a depressed index of contractility had impaired indexes (Fig. 5). It is therefore logical to propose that the changes in incremental elastance and in velocity of lengthening evidenced in this study were mainly caused by impaired LV relaxation. Furthermore, a reasonable hypothesis to explain this impaired relaxation is a depressed myocardial contractility in these patients.

However, factors other than the active relaxation process, such as the viscous properties or the restoring forces, might also explain these changes in ventricular elastance. The filling rates were higher in patients with valve disease than in normal subjects during this phase

(average values 412 versus 214 ml/s per m^2; $p < 0.01$), and these high filling rates certainly increased the viscous resistance in this setting. In addition, the viscous properties of the myocardium are known to increase with length in isolated muscle and in animals,[35,37] a finding that was recently confirmed in man.[38] Because the end-systolic volume is much greater in patients with valve disease (Table I), their early diastolic filling starts at a greater muscle length, and consequently the viscous effect is expected to be greater in such patients. Similarly, the elastic recoil of the myocardium is also expected to be reduced when the end-systolic volume is augmented, and this factor might also play a role in the observed changes. Finally, the possibility that the viscous properties of the hypertrophied myocardium could be abnormal should also be considered.

In summary, our data indicate that an impairment of LV elastance during early diastole generally is associated with changes in ventricular afterload and inotropic state. A large number of patients with apparently normal ventricular function still have normal incremental elastance, which can explain the overlap of incremental elastance among groups. Further studies are needed to clarify the respective roles of the active relaxation process, of the viscous properties, and of the restoring forces in determining these diastolic abnormalities.

Clinical implications: Effects of nifedipine: Our data indicate that at least 50% of the patients studied (Fig. 3) have impaired ventricular elastance during early diastole. The clinical implications of these observations are twofold. First, previous studies have suggested that similar abnormalities in early diastolic filling contributed to the patients' functional symptoms[14,17,18,22] and that interventions such as the administration of a calcium antagonist might improve these abnormalities and the patients' functional status.[17,18,22] In this perspective, our data indicate that the sublingual administration of nifedipine significantly enhanced the early diastolic properties (Fig. 1, Table III) together with the ejection fraction and the mean velocity of fiber shortening. Our findings also suggest that these beneficial effects might be related to a decreased afterload (−20 mm Hg in LV systolic pressure [$p < 0.01$] and −17% in peak wall stress [$p < 0.05$]) rather than to an increase in inotropic state. The index of inotropic state in our study was slightly depressed after administration of nifedipine. Accordingly, therapeutic interventions with afterload-reducing agents might deserve further investigations in patients with valvular regurgitation. These effects of nifedipine also support the hypothesis that incremental elastance mainly reflects ventricular relaxation. It is unlikely that nifedipine could acutely modify myocardial stiffness or viscosity. However, a decrease in afterload was expected to improve incremental elastance by accelerating relaxation.

Second, other studies have suggested that abnormalities of diastolic properties might be useful in detecting irreversible myocardial damage.[40] Therefore, it might be worthwhile to investigate postoperatively this diastolic phase in all patients with previously impaired ventricular elastance, After valve replacement, such an assessment could be easily performed noninvasively.[19,20–22]

In conclusion, our data indicate that a standardized index of LV elastance, computed during early diastolic filling, is abnormal in at least 50% of patients with valvular regurgitation. This approach is also able to detect abnormalities in diastolic filling in patients with heart disease. This index might therefore be useful in understanding the changes in myocardial function after valve surgery.

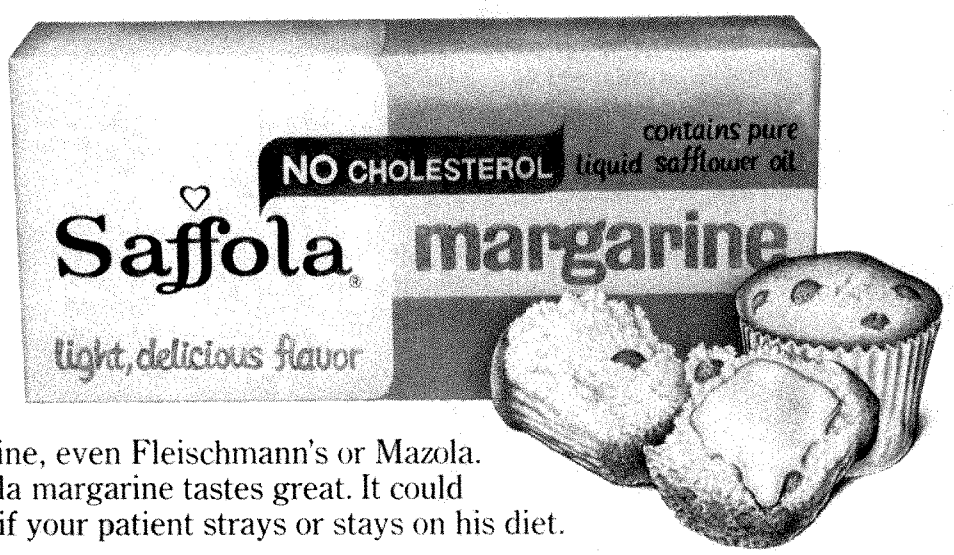
Cheer up a low cholesterol diet with Saffola.



Saffola margarine is perfect for your patients following a low-cholesterol diet.

First of all, Saffola has no cholesterol. And it is higher in beneficial polyunsaturates than corn oil margarine, even Fleischmann's or Mazola.

But because Saffola margarine tastes great. It could mean the difference if your patient strays or stays on his diet.

Absolutely no cholesterol and higher in beneficial polyunsaturates.

Second Clinical Conference on CONGENITAL HEART DISEASE

EDITED BY BERNARD L. TUCKER, M.D., GEORGE G. LINDESMITH, M.D., and MASATO TAKAHASHI, M.D.

This volume is based on presentations made at the Second Clinical Conference on Congenital Heart Disease held in Los Angeles in January 1981. It covers atrial and endocardial defects and the hemodynamics related to these disorders. Noninvasive diagnosis, surgical correction, and pathology are also heavily stressed.

1982, 448 pp., 146 illus., $29.50 ISBN: 0-8089-1507-x
Order Code: 794650

CONGESTIVE HEART FAILURE

CURRENT RESEARCH AND CLINICAL APPLICATIONS

EDITED BY EUGENE BRAUNWALD, M.D., MICHAEL B. MOCK, M.D., and JOHN WATSON, Ph.D.

This volume reports on our present understanding of the mechanisms and models of congestive heart failure, and, as well, on current medical and surgical-treatment therapies.

1982, 400 pp., 140 illus., $34.50 ISBN: 0-8089-1469-3
Order Code: 790657

TREATMENT OF INFECTIVE ENDOCARDITIS

EDITED BY ALAN L. BISNO, M.D.

This timely and pertinent volume presents a comprehensive analysis of the treatment of infective endocarditis.

1982, 352 pp., 21 illus., $34.50 ISBN: 0-8089-1450-2
Order Code: 790598

CARDIAC ULTRASOUND WORKBOOK

M-MODE AND TWO-DIMENSIONAL ECHOCARDIOGRAPHY

EDITED BY JAMES V. TALANO, M.D.

This practical workbook provides an in-depth examination of the applications and techniques of M-mode and two-dimensional echocardiography. It features illustrations and actual echocardiograms of normal and abnormal cardiac states.

1982, 272 pp., 176 illus., $19.50 ISBN: 0-8089-1437-5
Order Code: 794490

CLINICAL NUCLEAR CARDIOLOGY

EDITED BY DANIEL S. BERMAN, M.D., and DEAN T. MASON, M.D.

A Clinical Cardiology Monograph

"I recommend this textbook to specialists in cardiology and nuclear medicine who are interested in a comprehensive, clinically oriented review of the techniques of nuclear cardiology."

—Robert D. Okada, M.D. in *The New England Journal of Medicine*

1981, 512 pp., 277 illus., $49.00 ISBN: 0-8089-1356-5
Order Code: 790571

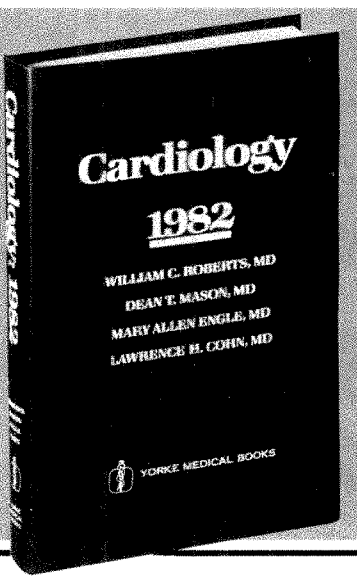
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung, & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, New York 11205 AJCK2

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)

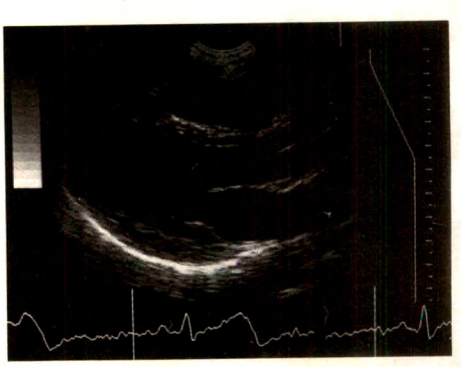
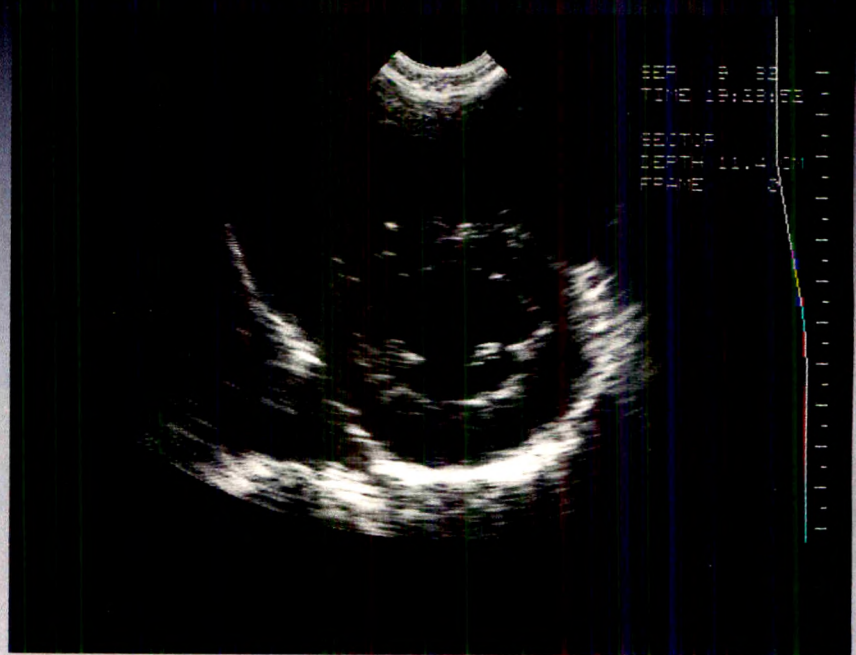
TODAY, ATL BRINGS A NEW GENERATION OF IMAGE QUALITY TO CARDIOLOGY.



SIX REASONS WHY ATL
THE INDUSTRY STANDAR



1. *Spatial Accuracy*
2. *Precise Definition of Wall Boundaries*
3. *Noise Free Cardiac Chambers*

Ever since 1979 when ATL introduced the first 2-D digital sector image, our image quality has been everyone's standard for comparison.

Today, with the introduction of CardioSeries,™ ATL presents the cardiologist with a new generation of echocardiography systems featuring the most accurate 2-D images available.

Here is image quality you can see: greater penetration, higher resolution, more precise definition of cardiac boundaries, detailed grey scale mapping and noise free chambers.

The 2-D echoes above illustrate these criteria clearly. We invite you to see a demonstration of ATL's new CardioSeries.

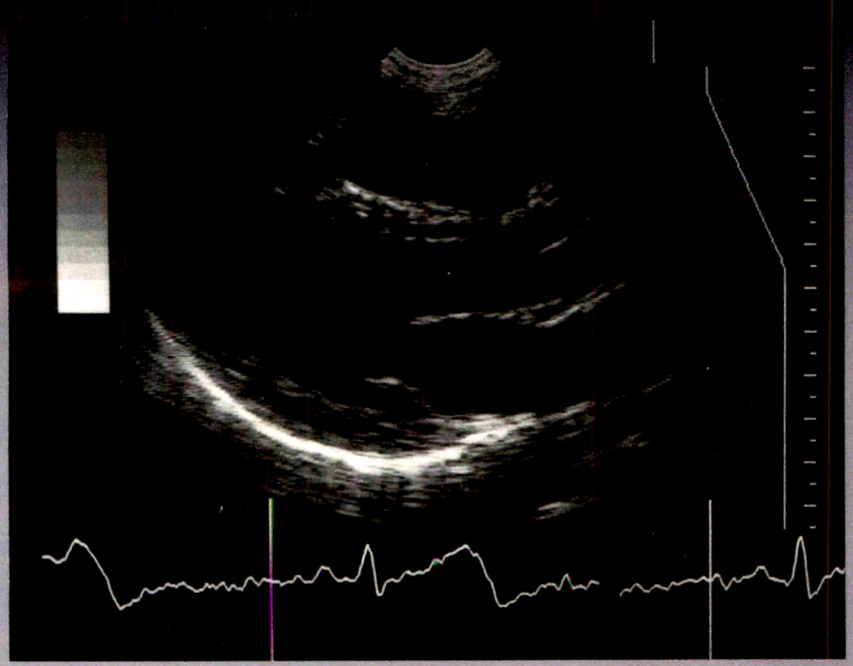
What you will see is a true advancement in 2-D image quality. An advancement made possible by technological improvements in the echo receiver, digital scan converter and scanheads. These improvements together provide a better collection of pure diagnostic data and therefore more precise echoes.

CardioSeries Takes High Resolution Ultrasound To Greater Depths. ATL's new CardioSeries provides increased penetration at all frequencies. Now, a greater percentage of adults, in addition to your pediatric patients, can be examined with excellent results using a 5 MHz scanhead.

Extended Grey Scale and Post Processing. With better than 7-bit image display precision, CardioSeries provides a very precise definition of cardiac wall boundaries, valves and most importantly, visualization of possible life threatening apical clots and thrombi.

Furthermore, eight post-processing functions enable optimal assignment of specific

NEW CARDIOSERIES IS FOR 2-D ECHOCARDIOGRAPHY.



4. *Near Field Resolution*
5. *Far Field Resolution*
6. *Detailed Grey Scale Mapping*

grey scale values anytime during the examination.

A New M-mode Concentrates On Your Concerns. The new M-mode of CardioSeries gives you more flexibility and information than ever before. The selectable pre-processing curves help focus on specific areas of interest. The M-mode's wide range grey scale presents greater tissue texture information, and selectable edge enhancement provides precise cardiac boundary definition without compromising the grey scale presentation.

A Direct Link To Off-Line Analysis. With CardioSeries you are one step closer to the future of off-line computer analysis. Each system includes a Data Port through which unprocessed digital image information can be transmitted to an external computer.

Add CardioSeries Capabilities To Your Existing ATL System. Enhance your MK 300 or MK 500 system performance and protect your original investment against obsolescence by upgrading with CardioSeries capabilities.

Compare ATL's performance with any other. Compare penetration, resolution and overall image quality. Decide for yourself which 2-D echo is best. Call ATL. We will demonstrate our CardioSeries echocardiography systems against any other.

ATL ultrasound

THE MEASURABLE ADVANTAGE IN ECHOCARDIOLOGY

NEW FROM ATL. CARDIOSERIES™— THE MEASURABLE ADVANTAGE IN ECHOCARDIOLOGY

CARDIOSERIES IS ANOTHER EXAMPLE OF ATL'S CONTINUING ADVANCEMENTS IN ECHOCARDIOLOGY.

CardioSeries is an improvement you can see, an improvement you can measure. This continuing effort for technical advancement is the reason more ATL echocardiography systems have been installed in the past three years than those of any other 2-D company.

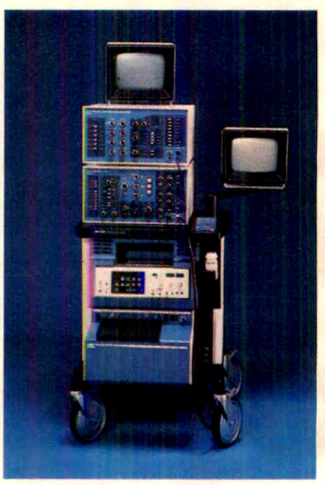
ATL, A CONSISTENT LEADER IN ECHOCARDIOLOGY.

- □ Founded in 1974
- □ First digital scan converter for Real-time ultrasound
- □ First 90° 2-D sector
- □ First pediatric 5 MHz 2-D probe
- □ First dual frequency Doppler system
- □ First duplex Doppler and Real-time system, 1978
- □ First clinically proven pulsed Doppler technology

CARDIOSERIES, A NEW GENERATION OF IMAGE EXCELLENCE.

- □ 90° full-view 2-D sector
- □ 16 precise depth settings
- □ Up to 45 frames per second
- □ Seven cardiology scanheads
- □ Selectable grey-scale M-mode
- □ Increased penetration and improved overall image quality
- □ Better than seven bit image display precision
- □ 8 post processing transfer curves.

The New CardioSeries MK 300LX, a low cost, dedicated 2-D ultrasound system.



The New CardioSeries MK 500 CX, a high performance 2-D, M-mode and pulsed Doppler ultrasound system.

The New CardioSeries MK 300C, a high performance 2-D, and M-mode ultrasound system.

Detection of Mild Aortic Regurgitation by Range-Gated Pulsed Doppler Echocardiography

RICARDO J. ESPER, MD

In order to assess the sensitivity and specificity of the range-gated pulsed Doppler echocardiogram for the detection of aortic regurgitation, a study with use of this technique was carried out in 46 patients. They were classified into 3 groups: *Group I* was composed of 19 patients with a variety of heart diseases but with a competent aortic valve. Cardiac catheterization revealed no aortic regurgitation in any of the 19 patients, and the Doppler echocardiogram detected no turbulent diastolic flow in the left ventricular outflow tract. *Group II* was composed of 17 patients who clinically and by auscultation had aortic regurgitation, which was confirmed by cardiac catheterization in 6. In all 17 patients the Doppler echocardiogram detected several grades of turbulent diastolic flow compatible with aortic regurgitation in the left ventricular outflow tract. *Group III* was composed of 10 patients with aortic regurgitation but without the expected clinical or auscultatory evidence. The echocardiogram detected mitral valve flutter in only 1 patient. Cardiac catheterization revealed aortic regurgitation graded 1/4 and 2/4 in 9 patients, and the patient who did not undergo catheterization had a murmur of aortic insufficiency 6 months later. In all 10 patients the Doppler echocardiogram detected a regurgitating turbulent flow compatible with aortic regurgitation in the left ventricular outflow tract.

It is concluded that the Doppler echocardiogram was more useful than auscultation and echocardiography for the detection of mild aortic regurgitation. In this study the range-gated pulsed Doppler echocardiogram proved 100% sensitive and specific. However, it will be necessary to study larger groups in order to assess its utility in more complicated conditions (obesity, emphysema, and heart failure) and the differential diagnosis with other diastolic murmurs.

Aortic valve insufficiency produces a variety of characteristic signs that are well known, but the most reliable sign is auscultation of an early diastolic murmur in the left parasternal area. However, on some occasions the characteristic murmur and peripheral signs are absent.[1-3] In these cases echocardiography may prove useful when it reveals diastolic flutter of the anterior leaflet of the mitral valve or of the left side of the interventricular septum,[4,5] but these findings are not consistent and aortography is required to make the diagnosis.[6] Under these circumstances, range-gated pulsed Doppler recording combined with either M-mode or 2-dimensional echocardiography may demonstrate the existence of pathologic diastolic turbulent flow in the left ventricular outflow tract below the aortic valve level, which can spread to the apex in cases of increased severity.[7]

The aim of the present study was to assess the sensitivity and specificity of the range-gated pulsed Doppler echocardiogram in the detection of pathologic diastolic subaortic turbulent flow in a group of patients with aortic insufficiency without an audible diastolic murmur. The findings were compared with findings in another group of patients with aortic insufficiency with a characteristic diastolic murmur. A third patient group without aortic insufficiency served as the control group.

From the External Graphic Records Section, Cardiology Service, Hospital Militar Central, and the Cardiology Division, Policlinica Bancaria, Buenos Aires, Argentina. Manuscript received December 2, 1981; revised manuscript received March 16, 1982, accepted May 6, 1982.

Address for reprints: Ricardo J. Esper, MD, Division Cardiología, Policlinica Bancaria, Avda. Gaona 2100, 1416 Buenos Aires, Argentina.

Methods

Study Patients

Forty-six patients classified into 3 groups were included in the study (Table I).

Group I: Competent aortic valve: The control group was composed of 19 patients, both male and female, affected by diverse forms of cardiopathy. None had clinical, auscultatory,

Angio = angiography; Ao = aortic valve; CHD = coronary heart disease; Diast = diastole; IHSS = idiopathic hypertrophic subaortic stenosis; M = mitral valve; R = regurgitation; S = stenosis; Tur flow = turbulent aortic regurgitant flow.

echocardiographic, or hemodynamic evidence of aortic valve regurgitation. Three of the patients had a prosthetic aortic valve; 2 were of the porcine type[8] (Cases 18 and 19) and 1 was of the dura mater type[9] (Case 17). In the 2 patients with aortic stenosis the cause was undetermined; the aortic valve gradient was 65 and 80 mm Hg, respectively. No patient had heart failure.

Group II: Aortic regurgitation with characteristic physical findings: This group was composed of 17 patients, both male and female, with chronic aortic insufficiency either isolated or in association with other abnormalities. They were classified clinically as mild, moderate, and severe, according to New York Heart Association functional criteria.[10] All had a regurgitant diastolic murmur characteristic of aortic insufficiency with amplitudes varying between grades 2/6 and 5/6.[11] Six of the 17 patients underwent cardiac catheterization which revealed aortic regurgitation graded 2/4 and 3/4, respectively.[12]

Three of the patients (Cases 20, 21, and 24) had associated mitral stenosis. Three other patients had a prosthetic valve of the biologic type in the aortic position; 2 of them were made of dura mater, and had been placed 4 and 5 years earlier (cases 30 and 31), and the third, a porcine valve, had been placed 8 months earlier.

Group III: Aortic regurgitation without detectable physical signs: This group was composed of 10 patients examined by at least 2 experienced cardiologists, but without any clinical signs suggesting aortic insufficiency. None had

a diastolic murmur of aortic regurgitation, in the supine or standing position, during deep expiration or during hand-grip test. Nine underwent cardiac catheterization, which revealed grade 1/4 regurgitation, except for 1 patient (Case 40) with grade 2/4 reflux. The 10th patient (Case 46) who did not undergo catheterization was later found to have a murmur of aortic insufficiency 6 months after this study was done.

Doppler Echocardiography

A range-gated pulsed Doppler examination was carried out in these 46 patients by the same physician using a commercially available instrument (Mark V, Advanced Technology Laboratories, Seattle, Washington) which makes it possible to obtain a Doppler recording along the same ultrasonic beam as the echocardiogram and from a teardrop-shaped region, called the sample volume. This point is positioned in the affected area by means of 2-dimensional echocardiographic imaging. The Doppler flow signal can be obtained in 2 ways: (1) through an auditory signal that makes it possible to differentiate between the soft sound of the laminar flow and the harsh sound of the pathologic turbulent flow, and (2) through a graphic recording that shows both the M-mode echocardiogram on which is superimposed a depth line indicating the location of the sample volume and the spectral time-interval histogram, where the different frequencies of the reflected ultrasonic beam are diagrammed like dots in a system of coordinates with respect to time. Laminar flows produce a dot pattern that inscribes a smooth curve, whereas turbulent flows generate a dispersed dot pattern, similar to the recording of murmurs in a phonocardiogram.[13,14] As in all recordings, the amplitude of the signals varies according to the selection of the Doppler instrument's threshold and gain controls. Thus both the experience of the operator and the standard values established by the laboratory are important. The lowest effective threshold was used together with a gain setting that would exclude excessive electronic noise.[15,16] Care was taken to limit the amplitude of the Doppler signal (lower tracing in all the figures) to show peaks and not plateaus; for this reason the controls were continuously adjusted for each patient to produce consistent results.[17–19] Flow was considered turbulent when the features of the auscultatory signals were characteristic, and if at the same time the dotted pattern of the time-interval histogram was over 1 cm wide.

Technique: The Doppler echocardiographic examination was of acceptable technical quality in all patients and was carried out no more than 2 weeks before catheterization. The patient's position varied from supine to semidecubitus or left lateral decubitus. First a 2-dimensional echocardiogram was performed scanning the long axis in the parasternal area with conventional techniques already reported.[20,21] Then a complete scan of the left ventricle by the M-mode method was obtained, and finally the Doppler flow signals were studied in the left ventricular inflow and outflow tracts as well as the aortic root. Special care was taken in studying the outflow tract of the left ventricle below the aortic valve, where a smooth systolic flow with features similar to those of the aortic root is usually obtained. In cases of aortic stenosis the systolic flow is turbulent, whereas in aortic insufficiency a harsh, turbulent, regurgitating diastolic flow can be appreciated from the audio signal and recorded graphically.[7] Special care was taken to avoid sampling near the aortic and mitral valves so as to avoid the clicks that are characteristic of the movement of these valves.[13,14] Mitral stenosis produces a turbulent diastolic flow in the left ventricular inflow tract which—when it is very intense—may be detected in the outflow tract and mistaken for aortic regurgitation. In these cases, special care was taken to place the sample volume and to assess the timing and auditory characteristics of the Doppler signal. In aortic regurgitation the signal appears earlier and decreases during diastole, whereas in mitral stenosis the auditory signals usually appear later and are sustained during the entire diastole. Since from the parasternal area the sample volume may be laid perpendicularly to the blood flow velocity and therefore no Doppler signal may be recorded, we proceeded to scan the left ventricular outflow tract and aortic root from the suprasternal area in all cases.

Cardiac catheterization: Catheterization was performed according to conventional methods and angiography was performed injecting contrast material into the aortic root. Special care was taken in the positioning of the catheter as well as in the pressure of the injection of contrast medium to avoid false aortic regurgitation produced by technical shortcomings. The severity of regurgitation was graded 0 to 4.[12]

Results

The patients in group I by definition lacked any clinical, auscultatory, or echocardiographic evidence of aortic regurgitation. Cardiac catheterization revealed no valve reflux (Table I).

In group II all the patients had a regurgitant diastolic murmur characteristic of aortic insufficiency. They were classified as mild, moderate, and severe according to the clinical, radiologic, and electrocardiographic findings. Cardiac catheterization confirmed aortic insufficiency in 6 patients, and the diagnosis was amply supported in other patients by noninvasive methods (Table I).

Group III was composed of patients with no clinical or auscultatory signs suggesting aortic regurgitation, except for 1 patient whose echocardiogram revealed the existence of mitral valve flutter. In 3 patients (Cases 37, 38, and 41) the diagnosis was made first by cardiac catheterization and after further reassessment the Doppler echographic examination revealed pathologic turbulent flow, characteristic of aortic regurgitation, in the left ventricular outflow tract. In the remaining 7 patients (Cases 39, 40, and 42 to 46) the diagnosis was obtained by Doppler echographic examination and was later confirmed by cardiac catheterization in 6.

Echocardiography—mitral valve flutter: In group I there was no evidence of mitral valve flutter. In group II 10 patients or 58.8% of the 17 patients exhibited mitral valve flutter. In group III only 1 patient (Case 43) demonstrated mitral valve flutter; this led to the presumption of aortic regurgitation, which was described as mild, and angiography detected a reflux graded 1/4.

Catheterization data: In group I no aortic reflux was noted in any of the 19 patients, which confirmed the clinical presumption. In group II only 6 patients had angiographic studies that revealed aortic regurgitation with severity graded 2/4 and 3/4. The other patients did not have hemodynamic studies because noninvasive diagnostic evidence was considered adequate, or valve insufficiency was too mild to warrant invasive studies. In the third group 9 patients underwent angiography revealing aortic regurgitation graded 1/4, except for 1 patient (Case 40) graded 2/4.

Doppler examination: In group I the Doppler examination revealed no pathologic turbulent diastolic flow in the left ventricular outflow tract either on

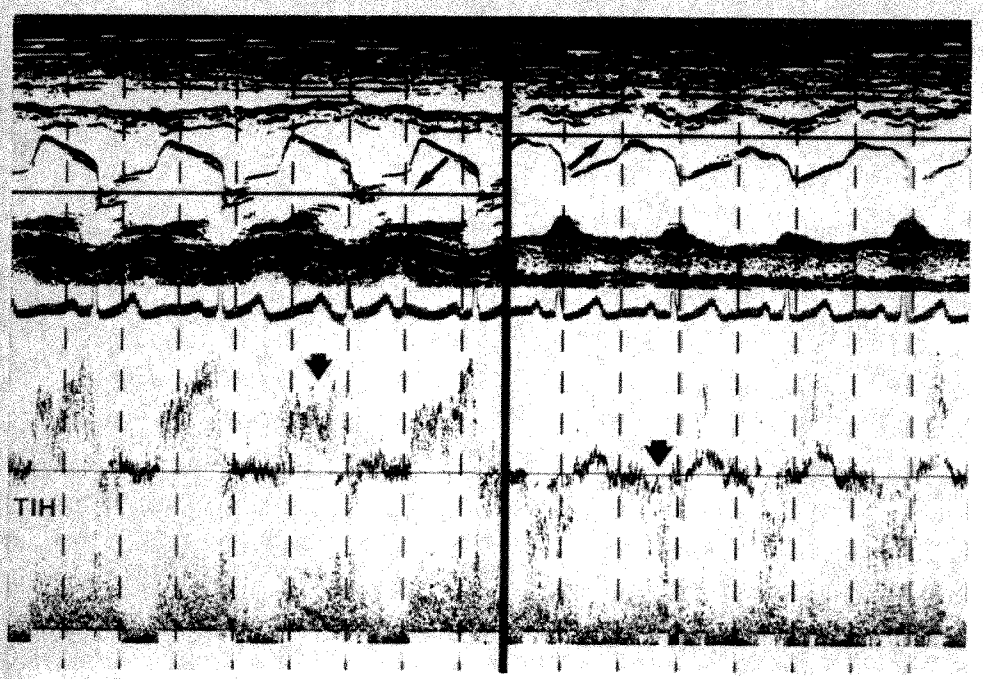

FIGURE 1. Patient 37 with rheumatic mitral stenosis and aortic insufficiency. **Left,** the sample volume (**thin arrow**) is placed in the left ventricular inflow tract, in front of the mitral valve, and the time interval histogram (TIH) shows turbulent flow of mitral stenosis (**thick arrow**). **Right,** the sample volume is placed in the left ventricular outflow tract (**thin arrow**) and a turbulent flow of aortic regurgitation is shown (**thick arrow**) in the time interval histogram.

scanning the parasternal area or from the suprasternal area. The 2 patients with aortic stenosis (Cases 15 and 16) and the 2 patients with idiopathic hypertrophic subaortic stenosis (Cases 10 and 11) exhibited turbulent systolic flow in the aortic root and in the left ventricular outflow tract. One of the patients with mitral valve prolapse (Case 8) and another with rheumatic mitral insufficiency (Case 14) exhibited turbulent harsh systolic flow in the left atrium near the mitral valve, and the 2 patients with mitral stenosis (Cases 12 and 13) had pathologic diastolic turbulent flow in the left ventricular inflow tract that did not spread into the outflow tract. The patients with biologic aortic prosthetic valves (Cases 17 to 19) had a mild turbulent flow in the aortic root, but it was not severe enough to be considered pathologic. The 7 patients with coronary heart disease (Cases 1 to 7) did not display pathologic turbulence.

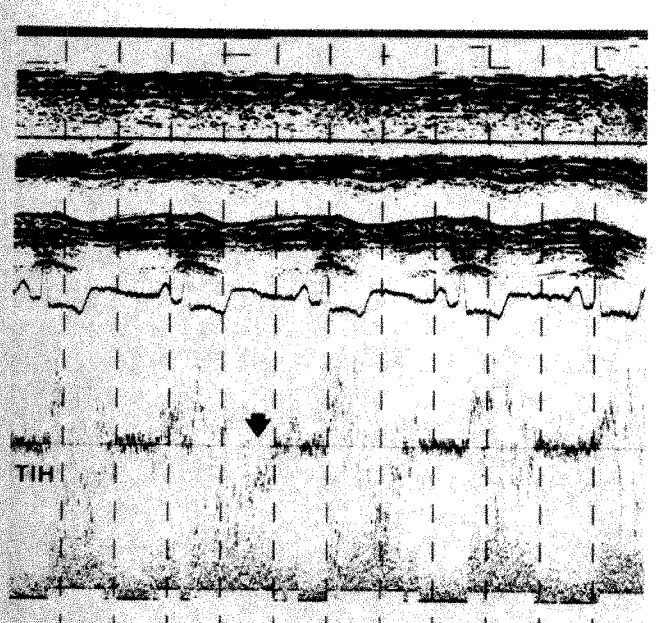

FIGURE 2. Patient 41 with calcified aortic stenosis. The sample volume (**thin arrow**) is placed in the aortic root above the aortic valve from suprasternal view. The time interval histogram (TIH) shows turbulent systolic flow of aortic stenosis and diastolic regurgitant flow of aortic insufficiency (**thick arrow**).

In group II all patients had diastolic turbulence in the left ventricular outflow (100%) detected from both the parasternal and suprasternal areas. In some of them the flow extended to the apex. The patients with mitral stenosis also had turbulent flow in the left ventricular inflow tract, distinct in timing and characteristics from that of aortic regurgitation. The 2 patients with an aortic congenital bicuspid valve (Cases 27 and 28) and those with an aortic prosthetic valve (Cases 30 to 32) revealed systolic turbulence that was too low in amplitude to be regarded pathologic.

In group III all patients showed a mild diastolic turbulence in the left ventricular outflow tract detected from both the parasternal and suprasternal areas. The 4 patients with added mitral stenosis (Cases 37 to 40) also had diastolic turbulence in the left ventricular inflow tract, distinct from that produced by aortic reflux (Fig. 1). The 2 patients with calcific aortic stenosis had clear pathologic systolic turbulent flow, but neither the patient with congenital aortic bicuspid valve (Case 43) nor the ones with aortic prosthetic valve revealed pathologic systolic flow patterns (Fig. 2).

Discussion

In aortic valve insufficiency, the regurgitant blood flow generates turbulence which produces the diastolic murmur that is the hallmark of this disease. However,

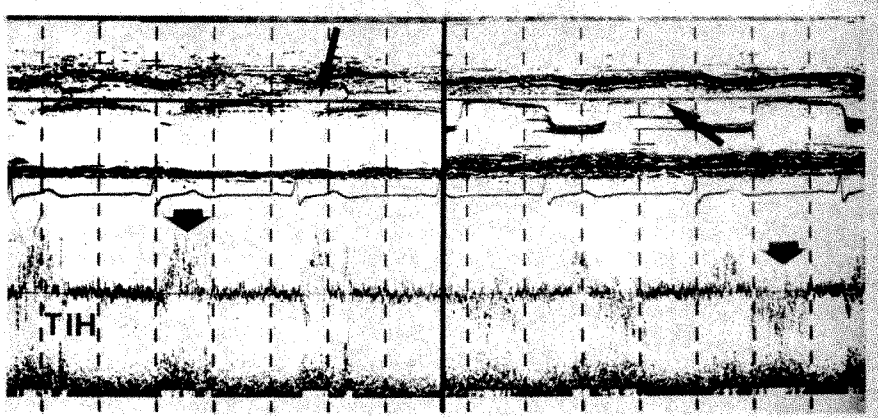

FIGURE 3. Patient 39 with rheumatic mitral and aortic valvulopathy. **Left,** the sample volume is placed in the aortic root, through the aortic valve (**thin arrow**), showing systolic aortic turbulent flow (**thick arrow**) in the time interval histogram (TIH). **Right,** the sample volume is in the left ventricular outflow tract (**thin arrow**), showing a turbulent diastolic flow of aortic regurgitation (**thick arrow**) in the time interval histogram.

in mild regurgitation the murmur may not be heard, especially in patients who are obese or have pulmonary emphysema.[1,3] The murmur may also diminish in cases of left ventricular failure when the reduction in left ventricular compliance and the increase in left ventricular end-diastolic pressure reduce the regurgitation. In cases of mitral stenosis or severe aortic stenosis the clinical and auscultatory signs of aortic insufficiency may be concealed or altered so as to become inapparent.[1–3] Thus, mild aortic insufficiency with atypical clinical manifestations and no audible murmur may go unnoticed or turn up as a chance finding in cardiac catheterization.[6]

The range-gated pulsed Doppler echocardiogram allows detection of turbulence of the bloodstream in the left ventricular outflow tract produced by regurgitation.[7] Turbulence, in turn, is thought to be the cause of the murmurs. The limitations that may prevent our obtaining a technically useful echocardiogram are also operative for the Doppler examination. In the present study only those patients who had a satisfactory Doppler echocardiogram were included. However, no patient was extremely obese and none had pulmonary emphysema, which might have suppressed the auscultatory phenomena.

Diagnostic role of Doppler echocardiogram in the absence of a diastolic murmur: It might be assumed that the aortic insufficiency in the patients in group III was very mild and therefore no murmur could be heard. However, 1 patient (Case 40) exhibited angiographic aortic regurgitation graded 2/4, and another (case 43) had mitral valve flutter in the echocardiogram. In contrast, 5 patients in group II (Cases 26, 28, 30, 32, and 34) had aortic insufficiency that might be described clinically as mild (that is, without electrocardiographic or radiologic abnormalities and with a diastolic murmur of aortic insufficiency as the only finding). Only 1 of these patients (Case 26) had mitral valve flutter in the echocardiogram (20% of the mild cases). This finding leads to the assumption that in patients in group III, the sound energy produced by the turbulence of the regurgitating jet was not intense enough to produce an audible murmur. Furthermore, all the patients in group III were examined by at least 2 experienced cardiologists, and the additional examinations were carried out retrospectively to make certain that minimal signs had not been overlooked. Reinforcement of the suspected murmur signs was produced by altering the patient's position and respiration and by hand-grip exercise. Although phonocardiographic records were obtained, these were not mentioned because it is well known that in the specific case of aortic insufficiency, murmurs are not always recorded because of their high pitch and low intensity, the human ear being more sensitive.

In the patients in our study, the various cardiac abnormalities other than aortic regurgitation that were encountered such as mitral stenosis, mitral insufficiency, aortic stenosis, mitral valve prolapse and idiopathic hypertrophic subaortic stenosis yielded Doppler records, all of which were characteristic and consistent with the clinical diagnoses and cardiac catheterization findings. This observation led to the assumption that the technique that was used was satisfactory in these assorted groups of patients for the correct diagnosis of their complaints (Fig. 3).

Assessing the severity of aortic regurgitation: Other investigators have been able to assess the direction of the jet and the severity of regurgitation in patients with mitral insufficiency by scanning the left atrium with the sample volume of the range-gated pulsed Doppler recording.[22,23] In aortic insufficiency it is possible to have an idea of the severity by detecting the dispersion or distribution of the turbulent regurgitating flow. In mild cases it confines itself to the left ventricular outflow tract, in moderate cases it invades the inflow tract, and in severe cases it can reach the apex.[24] But this exploration encounters certain restrictions and demands that no other valve disease exist (as in the case of mitral stenosis in which the jets overlap) and that the left ventricle be dilated in such a way as to prevent the anterior leaflet of the mitral valve from contacting the interventricular septum and hindering the scanning of the sample volume. The possible impact of these factors could not be studied in the present investigation. However, in all patients in group III the turbulence was confined to the left ventricular outflow tract, suggesting that regurgitation was mild in all.

Associated abnormalities: Probably some associated pathologic conditions favor the detection of diastolic turbulent flows resulting from aortic regurgita-

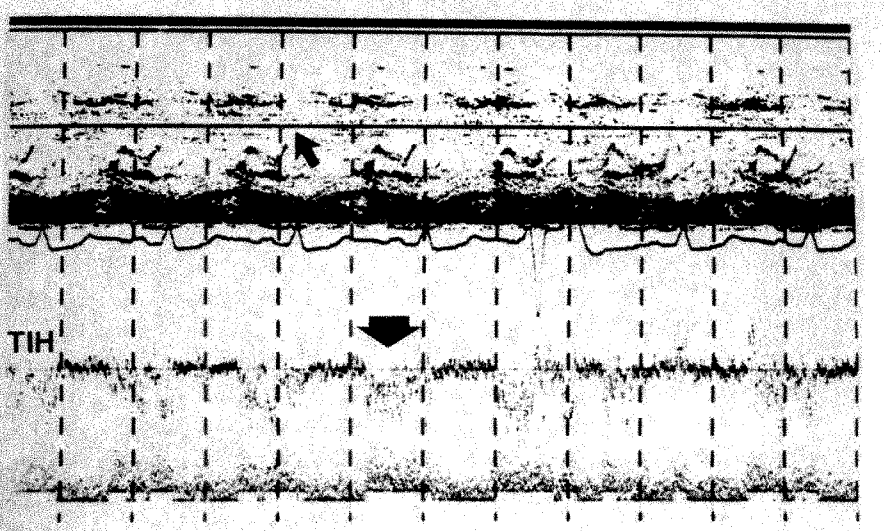

FIGURE 4. Patient 46 with a biologic aortic prosthesis, who had an audible murmur of aortic regurgitation after 6 months. The sample volume (**thin arrow**) is placed in the left ventricular outflow tract, and the time interval histogram (TIH) shows a turbulent flow of aortic regurgitation (**thick arrow**).

tion, whereas other conditions have a detrimental effect. In the present study, however, patients in groups I and II had associated valve conditions similar to those of group III, such as mitral stenosis, mitral insufficiency, aortic stenosis, congenital bicuspid aortic valve, and biologic prostheses of dura mater and porcine valve. It is widely assumed that mitral stenosis hinders the recording of aortic insufficiency by range-gated pulsed Doppler examination. However, in these patients it was possible to discern both flows (Fig. 1).

Doppler recording versus auscultation: One patient in group III (Case 46) had a characteristic diastolic murmur of aortic regurgitation that was heard in a routine check-up 6 months after the first Doppler echographic examination. Results suggested that damage to the prosthetic valve was progressive, thus generating an increase in the sound energy so as to make the murmur audible (Fig. 4). In the same way, a mild but distinct murmur of aortic insufficiency was heard in another patient (Case 39) with mitral stenosis 8 months after operation.

The patients in group II who were diagnosed as having aortic insufficiency without confirmation by cardiac catheterization require a word of explanation. Auscultation demonstrated the typical murmur. The physicians in charge rejected the option of catheterization because the leak was considered mild. Isolated pulmonary valve regurgitation, a rare cause of a similar murmur, was considered highly unlikely. It may be concluded that both the Doppler recording and auscultation detect the same phenomenon; however, the Doppler recording proved more sensitive in detecting turbulence in the left ventricular outflow tract.

In the present study the 19 patients in group I, clinically and angiographically proved without aortic insufficiency, had no turbulence in the left ventricular outflow tract according to the Doppler recording, whereas all 17 patients in group II with aortic insufficiency had reflux. In group III all patients had mild aortic insufficiency (grade 1/4) except for 1 with moderate insufficiency (grade 2/4), but none had an audible diastolic murmur of regurgitation. The Doppler recording, however, proved useful in detecting the diastolic turbulent flows in all patients.

Clinical implications: Our findings give the range-gated pulsed Doppler echocardiogram a 100% sensitivity and specificity capacity for the detection of aortic insufficiency. However, it would be presumptive to claim that the method is 100% sensitive and specific in all instances without further evidence. In this study the 49 patients were selected because a technically adequate Doppler echocardiogram could be obtained. Patients were neither obese nor emphysematous, and those with heart failure were excluded.

It will be necessary to carry out studies with larger groups to ascertain the ultimate sensitivity and specificity of the method, but in our hands the range-gated pulsed Doppler echocardiogram proved far more sensitive than auscultation and echocardiography for the detection of mild aortic valve regurgitation. The detection of paravalve regurgitation and the utility of the method for differential diagnosis from other diastolic murmurs with similar features still remain to be assessed.

Acknowledgment

I express my gratitude to Ernest Craige, MD, Chapel Hill, North Carolina, and Donald Baker, EE, Seattle, Washington, for their careful assessment used in the preparation of this study.

Large V Waves in the Pulmonary Wedge Pressure Tracing In the Absence of Mitral Regurgitation

AUGUSTO D. PICHARD, MD, RICHARD KAY, MD, HARRY SMITH, PhD, PETER RENTROP, MD, JAMES HOLT, MA, and RICHARD GORLIN, MD

The accurate diagnosis of mitral regurgitation has important therapeutic implications. We have observed that large V waves in the pulmonary wedge pressure (PW) may be misleading in the diagnosis of mitral regurgitation. Of 237 consecutive patients with high quality hemodynamic, angiographic, and echocardiographic data, 27 had large V waves (peak V 10 mm Hg greater than pulmonary wedge mean pressure). Ventriculograms were analyzed in blind fashion by 3 expert angiographers for any angiographic evidence of mitral regurgitation; 17 patients had mitral regurgitation (group I), and 10 did not (group II). The control group (group III) of 22 patients had normal V waves and no mitral regurgitation. Twenty-two hemodynamic and echocardiographic variables were compared among groups. The only significant difference between groups I and II was in the slope of the ascent of the V wave (74.3 versus 141.9 mm/s, p = 0.021), also expressed as the mitral regurgitation index (6.01 versus 9.45, p = 0.005). A slope of 100 mm/s or slower had a sensitivity of 80% to confirm mitral regurgitation and a specificity of 70% to rule it out. The size of the V wave and the V/PW mean ratio were similar in groups I and II (38.5 ± 11 versus 37.5 ± 11 mm Hg, and 1.67 ± 0.3 versus 1.69 ± 0.4, respectively, p = NS) and were not helpful in predicting the presence or absence of mitral regurgitation. Among patients without mitral regurgitation (groups II and III), those with large V waves had a higher pulmonary wedge mean pressure (23.5 versus 15.6 mm Hg, p = 0.01), a higher A wave (25.3 versus 16.4 mm Hg, p = 0.032), a more elevated mitral regurgitation index (9.45 versus 3.99, p = 0.001), a larger left atrial size (24.5 versus 21.6 cc, p = 0.05), a greater V wave to pulmonary wedge mean pressure ratio (1.69 versus 1.10, p = 0.001), and a faster slope of ascent of the V wave (141.9 versus 53.05 mm/s, p = 0.005).

We conclude that large V waves in the pulmonary wedge pressure tracing can be seen in the absence of mitral regurgitation. The size of the V wave is related to factors that determine left atrial compliance. Caution is called for in the diagnosis of mitral regurgitation by pulmonary wedge pressure alone.

Hemodynamic monitoring is commonly used in the management of critically ill patients.[1,2] Information about the filling pressure of the left ventricle is obtained by evaluating the pulmonary wedge pressure or the pulmonary artery diastolic pressure.[3,4] Large V waves on this pulmonary wedge tracing are often interpreted as secondary to mitral regurgitation, and therapeutic decisions are based on this assumption.[5,6] We have observed a number of instances in which a large V wave recorded in the catheterization laboratory was not associated with angiographic or clinical mitral regurgitation.[7] The present study was designed to evaluate the prevalence of absent mitral regurgitation in patients with large V waves, and to gain some insight into the pathogenesis of a large V wave in the absence of mitral regurgitation.

Methods

Study patients: All patients undergoing right and left heart catheterization with angiography in our laboratory between June 30, 1979 and December 31, 1980 were studied. There were 300 patients. Sixty-three were excluded for 1 or more of

the following reasons: (1) poor quality or absent pulmonary wedge tracing (damaged tracing, unclear calibration, etc.); (2) unavailable echocardiogram or tracings of suboptimal quality that did not allow precise measurements of the dimensions of the left atrium and left ventricle; or (3) absent or inadequate left ventriculogram for analysis of possible mitral regurgitation (premature ventricular beats, poor visualization of the area of the mitral valve and left atrium); and (4) presence of mitral regurgitation secondary to rupture of the mitral valve apparatus. Ruptured chordae or papillary muscle was diagnosed by clinical, hemodynamic, and angiographic variables, such as a murmur of mitral regurgitation that appeared suddenly, with typical echocardiographic findings, with a peaked, giant V wave and often with angiographic demonstration of a flail leaflet. Therefore, 237 patients remained in the study.

Patient groups: The study patients were divided into 2 groups according to the presence or absence of large V waves on the pulmonary wedge tracing. A large V wave defined by a peak pressure of 10 mm Hg or greater than the mean pulmonary wedge pressure was present in 27 patients. The groups were further divided according to the presence or absence of mitral regurgitation on the left ventriculogram: group I, large V wave with mitral regurgitation; group II, large V wave without mitral regurgitation. Of the remaining 210 patients, a random sample of 22 patients was used as the control: group III, normal V wave with no mitral regurgitation; and group IV, normal V wave with mitral regurgitation.

Measurements: Catheterization was performed in the postabsorptive state, under premedication with diazepam, 10 mg orally. Right heart catheterization was performed with a Swan-Ganz catheter, and pressures were recorded with an Electronics for Medicine DR 12 recorder at a paper speed of 50 and 100 mm/s. Fluid-filled lines and P23D Statham transducers were used. The mid-chest was used as a reference point for calibration of zero. Pulmonary wedge pressure was obtained by inflating the balloon of the Swan-Ganz catheter in the pulmonary artery and advancing it until wedge pressure was seen. If damped pressure was obtained, a new position was attempted and lines were carefully flushed. The A, V, and mean pulmonary wedge pressures were measured in millimeters of mercury. Cardiac output was determined by thermodilution with the Swan-Ganz catheter; a minimum of 3 measurements were averaged. Aortic and left ventricular pressures were also obtained with fluid-filled systems and P23D Statham transducers. Aortic and left ventricular systolic pressures were read as peak systolic pressures. Aortic diastolic pressure was measured at the lowest point in diastole. Left ventricular end-diastolic pressure was measured at the peak of the R wave on the electrocardiogram. The mitral regurgitation index was determined by the method of Libanoff and Rodbard[8]: mitral regurgitation index = (V wave ascent slope in mm Hg/0.02 second)/cardiac index (liters/min/m^2 body surface area). The slope of ascent of the V wave was calculated by dividing the height of the V wave in mm Hg by the time elapsed from the start to the peak of the V wave.

Cineventriculography: The procedure was performed in the 30° right anterior oblique and 60° left anterior oblique projections and filmed at 30 frames/s, using 40 ml of 76% Renografin® (meglumine diatrizoate). A steeper right anterior oblique projection was used when the spine overlapped the mitral valve in the 30° right anterior oblique view. The ventriculograms were reviewed independently by 3 expert angiographers, without knowledge of the clinical or hemodynamic data. Mitral regurgitation was defined as present when any amount of contrast agent was visualized in the left atrium during ventricular systole. Premature beats or postextrasystolic beats were not analyzed. Cases in which the quality of the ventriculogram was less than optimal or in which the area of the mitral valve and left atrium was not clearly visualized were excluded. The 3 observers agreed on the presence or absence of mitral regurgitation in all cases except 1; this case was eliminated from the study population. Ejection fraction was calculated using the formula: EF = (EDV − ESV) EDV, where ESV = end-systolic volume and EDV = end-diastolic volume; the area-length method[9] was used to calculate left ventricular volume.

Echocardiography: M-mode echocardiograms were obtained before catheterization in all patients, with an Irex Medical System at 50 mm/s paper speed. Left ventricular dimensions were measured according to the standard convention[10] which includes the endocardium in the measurement. Left ventricular diameter and thickness of the interventricular septum and left ventricular posterior wall were measured in diastole at the peak of the R wave on the electrocardiogram. Left ventricular wall stress was evaluated as peak systolic stress by the formula[11–13]: Peak stress = (SBP × LVID)/h × [1 + (h/LVID)], where SBP = systolic blood pressure, LVID = left ventricular internal dimension, and h = thickness of interventricular system plus posterior wall divided by 2. Left ventricular mass was calculated by the formula[14]: Left ventricular mass = 0.77×10^{-3} [(LVID + LVPW + IVS)^3 − LVID^3] + 2.4, where IVS = interventricular septal thickness and LVPW = left ventricular posterior wall thickness.

A ratio of left atrial dimension by echocardiography to mean pulmonary capillary wedge pressure was created to obtain an indirect index of the compliance of the left atrium. The ratio V wave/pulmonary wedge mean pressure was calculated to evaluate the relative size of the V wave.

Sensitivity was defined as the ability of a test to correctly identify mitral regurgitation. Sensitivity = true positive/(true positive + false negative). Specificity was defined as the ability of a test to correctly identify those without mitral regurgitation. Specificity = true negative/(true negative + false positive).

Statistical analysis: The data were stored and analyzed using SAS (Statistical Analysis System) on an IBM 370 computer at the City University of New York Computing Center. The group means were compared using analysis of variance and Duncan's multiple range test. Two-tailed *t* tests were also calculated between groups. When required, a 2-tailed *t* test for unequal variances was used. Observed probability levels less than 0.001 were reported as 0.001 in this study. Stepwise discriminant function analysis was used to determine what measurement or combination of measurements best discriminates between patients with a large V wave and mitral regurgitation and those with a large V wave without mitral regurgitation.

Results

Of the 27 patients with large V waves, 17 (63%) had mitral regurgitation on the left ventriculogram (group I) and 10 patients (37%) did not (group II). Of the 22 patients without a large V wave, none had mitral regurgitation (group III). There were no patients in group IV (normal V wave, mitral regurgitation present) as a result of the random distribution by chance.

Group II (large V wave, no mitral regurgitation) included 3 patients with mitral stenosis, 1 with aortic stenosis, 1 with aortic stenosis and mitral valve pros-

TABLE I Clinical, Hemodynamic, and Echocardiographic Characteristics in the 3 Groups*

* Values are mean ± standard deviation. Group I = large V wave, mitral regurgitation; group II = large V wave, no mitral regurgitation; group III = normal V wave size, no mitral regurgitation.
EDP = end-diastolic pressure; IVS = interventricular septal thickness; LA = left atrium; LV = left ventricle; LVEDP = left ventricular end-diastolic pressure; LVID = left ventricular internal diameter; LVPW = left ventricular posterior wall thickness; MRI = mitral regurgitation index; PW = pulmonary wedge pressure; V = V wave.

thesis, 2 patients with aortic regurgitation, 2 with coronary artery disease, and 1 patient with patent ductus arteriosus.

Group III (normal V wave, no mitral regurgitation) included 4 patients with coronary artery disease, 7 with coronary artery disease and mild to moderate congestive heart failure, 1 with congestive cardiomyopathy, 1 with idiopathic hypertrophic cardiomyopathy, 4 with aortic stenosis, 3 with mitral stenosis, and 2 with aortic regurgitation.

Clinical hemodynamic, and echocardiographic data: Table I summarizes the clinical, hemodynamic, and echocardiographic data in group I (large V wave, mitral regurgitation), group II (large V wave, no mitral regurgitation), and group III (no large V wave, no mitral regurgitation). Table II shows the comparison of the 3 groups by Duncan's multiple range test. For each variable, the underlined groups have no statistically significant difference ($p < 0.05$).

Groups I and II, all with large V waves, were similar (without statistical significant difference) in the following variables (Table I): age, sex, incidence of atrial fibrillation, aortic systolic and diastolic pressures, left ventricular systolic and end-diastolic pressures, pulmonary wedge mean pressure, A and V wave height, cardiac index, ejection fraction, dimension of left atrium, left ventricular internal diameter, septal and posterior wall thickness by echocardiography, left ventricular mass, peak systolic stress, ratio of left atrial size to pulmonary wedge pressure, and the ratio V/pulmonary wedge mean pressure. The significantly different variables between groups I and II were the mitral regurgitation index (6.01 versus 9.45, $p = 0.005$) and the slope of ascent of the V wave (74.3 versus 141.9 mm/s, $p = 0.021$).

Slope of rise of V, mitral regurgitation index, and relative size of V wave (Fig. 1): To evaluate the best discriminatory value of a large V wave in proving or ruling out the presence of mitral regurgitation, we calculated the sensitivity and specificity of a continuous scale for (1) the slope of rise of the V wave, (2) the mitral regurgitation index, and (3) the relative size of the V wave (V wave/pulmonary wedge mean pressure ratio) (V/PW). Using the stepwise discriminant function procedure, the slope of ascent of the V wave was the measurement most useful in discriminating between

Abbreviations as in Table I.

patients with a large V wave with and without mitral regurgitation [$F(1,25) = 10.682$, $p < 0.01$]. Using a slope of 90 mm/s as a cutoff point for the presence (slope less than 90) or absence (slope greater than 90) of mitral regurgitation, 17% of patients with and 80% of patients without mitral regurgitation were diagnosed correctly. For the mitral regurgitation index, a cutoff point of 8 (greater than 8 = no mitral regurgitation, less than 8 = mitral regurgitation) had a sensitivity of 82% and a specificity of 70%. The V/PW mean ratio did not allow a useful separation between patients with and those without mitral regurgitation, which was expected because both groups have a similar mean V/PW ratio (Table I).

Large V wave in absence of mitral regurgitation: To evaluate the factors that may participate in the pathogenesis of a large V wave in the absence of mitral regurgitation, comparisons were made between groups II and III (all without mitral regurgitation). The correlations between the magnitude of the V wave (mm Hg) and all other echocardiographic and hemodynamic variables were determined. Table III summarizes the variables that have a statistically significant correlation. The statistically significant different variables were the height of the A and V waves, the mitral regurgitation index, the ratio V wave/pulmonary wedge mean pressure, the slope of ascent of the V wave, mean pulmonary wedge pressure, and the size of the left atrium. Both groups had similar age, sex, aortic systolic and diastolic pressures, cardiac index, ejection fraction, echographic left ventricular dimensions (septum, posterior wall, and internal diameter), left ventricular mass, peak stress, and the ratio of left atrial size to pulmonary wedge mean pressure.

Discussion

Previous studies: The V wave on the venous pulse was first described by McKenzie[15] in1902. It represents passive filling of the left atrium during ventricular systole, peaking just before the mitral valve opens. Normally, the V wave is slightly larger than the A wave in the left atrium; although slightly damped and phase delayed, the V wave as recorded from the pulmonary wedge position is an accurate representation of the V wave in the left atrium.[16,17] A large V wave has been considered typical of mitral regurgitation,[18,19] and a number of indexes have been reported to correlate the size and morphology of the V wave with the severity of mitral regurgitation. Kent et al.[20] suggested that V waves 5 mm Hg or greater than the C wave indicate mitral regurgitation, but Wells[21] proved this inaccurate; although most patients with severe mitral regurgitation

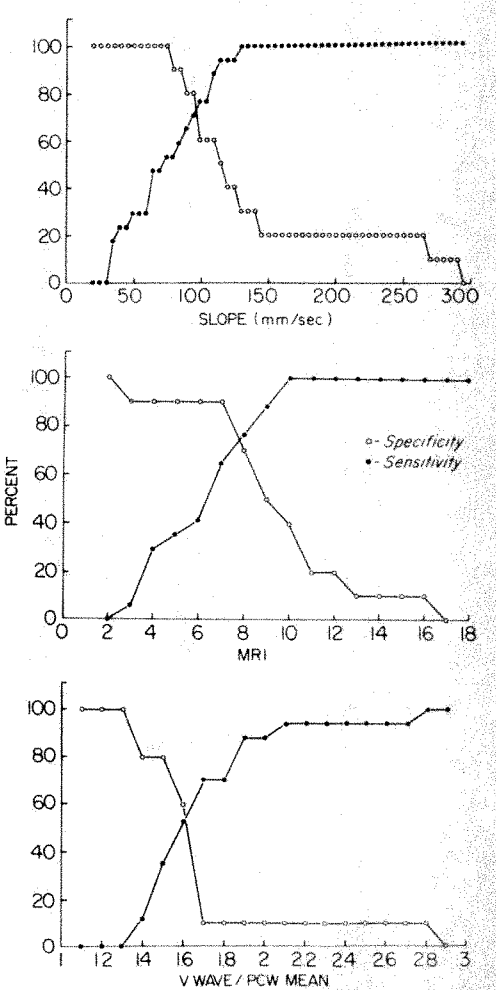

FIGURE 1. Sensitivity and specificity curves for the entire study population. The **vertical axis** shows the percent of sensitivity and specificity. The **horizontal axis** shows the slope of ascent of the V wave (**top**), the mitral regurgitation index (**middle**), and the V/pulmonary wedge mean pressure (PCW) ratio (**bottom**).

fit the rule, many patients with mild or absent mitral regurgitation also had a V-C wave difference greater than 5 mm Hg. Connolly and Wood[22] studied the ratio of peak V/mean pulmonary wedge pressure and found it a good index to separate patients with mitral regurgitation from those with mitral stenosis or from normal patients, but only if the mean pulmonary wedge pressure was 20 mm Hg or greater. When this pressure was lower, they exercised the patients to elevate the wedge pressure and were able to use the index reliably. These results have also been disputed.[23]

Libanoff and Rodbard[8] also tried to differentiate mitral stenosis from mitral regurgitation by creating a mitral stenosis index and a mitral regurgitation index. The mitral regurgitation index measures the slope of the rise of the V wave and divides it by the cardiac index because the more severe the mitral regurgitation, the greater the reduction in forward cardiac index. Using this index they were able to differentiate predominant mitral regurgitation from predominant mitral stenosis.

Formulas relating the rate of Y descent to the height of the V wave[24] or to mean left atrial pressure[25] are concerned more with the severity of obstruction to atrial emptying than with the severity of mitral regurgitation.

Variables relating a large V wave to the presence or absence of mitral regurgitation: We have observed that a large V wave in the pulmonary wedge pressure tracing often is not associated with mitral regurgitation.[7] In this study we confirmed that observation and found that 37% of patients with large V waves have no clinical or angiographic evidence of mitral incompetence. These patients had a wide variety of other cardiac diseases. When analyzing all patients with large V waves, we found that the only significant differences between those with mitral regurgitation (group I) and those without it (group II) were in the slope of ascent of the V wave (group I: 74.3; group II: 141.9; $p = 0.021$) and in the mitral regurgitation index of Libanoff and Rodbard[8] (group I: 6.01; group II: 9.45; $p = 0.005$). The absolute size of the V wave as well as its size relative to the mean pulmonary wedge pressure were not significantly different in the 2 groups (Tables I and II). The best discriminant value for slope of ascent was 90 mm/s, for mitral regurgitation index 8, and for the V/PW ratio 1.6. The slope had the best predictive value for mitral regurgitation with a sensitivity of 70% and a specificity of 80%. However, none of the variables allowed us to confirm or discard the presence or absence of mitral regurgitation with 100% accuracy. The size of the V wave and the ratio V/PW mean were similar in groups I and II (38.5 ± 11 versus 37.5 ± 11 mm Hg and 1.67 ± 0.3 versus 1.69 ± 0.4, respectively, p = NS) and were not helpful in predicting the presence or absence of mitral regurgitation.

Mechanism of a large V wave in the absence of mitral regurgitation: Looking for an explanation of why among patients without mitral regurgitation, some have a large V wave and some do not, we compared patients from group II (large V wave, no mitral regurgitation) with patients in group III (no mitral regurgitation, no large V wave) and found that patients in group II had a significantly higher mean pulmonary wedge pressure, a left atrium of larger size, a greater mitral regurgitation index, a faster slope of ascent, and a larger A wave than those in group III. These findings can be explained by considering the characteristic compliance of the left atrium and pulmonary veins as well as the other factors that determine the height of the V wave. The volume/pressure relation of the left atrium and pulmonary veins is not linear and can be depicted by a curve (Fig. 2) whereby small changes in volume produce little change in pressure when the left atrial or pulmonary wedge pressure is low, but a small change in volume is associated with a large change in pressure at the high pressure end of the curve. This compliance curve is characteristic of venous tissue,[26–29] and varies widely from patient to patient.[27,30] In our study, patients with a large V wave and no mitral regurgitation had an abnormally elevated pulmonary wedge pressure (mean 23.5 ± 8 mm Hg), so they were probably at the upper end of the compliance curve of the pulmonary venous left atrial system, resulting in a large V wave during atrial filling. In fact, the size of the V wave had a significant correlation with the magnitude of the pulmonary wedge mean pressure in all 3 groups (Table III). The large V wave in group II occurred despite a larger left atrial size than that in group III. This finding indicates that a high distending pressure may be present in a left atrium of any size[31,32] depending on the characteristic compliance of the left atrium and pulmonary venous system. The size of the left atrium may be related more to the duration and nature of the pathologic process (that is, rheumatic heart disease) than to the left atrial pressure.

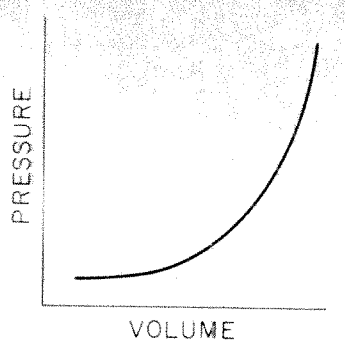

FIGURE 2. Compliance curve in the left atrium and pulmonary venous system. At the right end of the curve, small changes in volume are accompanied by large changes in pressure.

The slope of ascent of the V wave and the mitral regurgitation index were steeper (faster) in patients without mitral regurgitation than in those with mitral regurgitation (group II versus group I). Although this finding is unexpected, it could be explained as follows: patients without mitral regurgitation who had a high V wave (group II) are in such a steep portion of the pulmonary venous-left atrium compliance curve that the change in pressure occurs very rapidly as the atrial

volume increases toward the end of ventricular systole. However, in patients with mitral regurgitation the upstroke of the V wave begins earlier, with obliteration of the X descent[21] and a slower rate of rise toward its peak.

The size of the V wave is determined by a number of factors in addition to the compliance of the venous system[33–35]: (1) the initial volume of blood contained in the pulmonary venous-atrial system, (2) the rate of forward flow of blood to the left atrium, (3) the systemic arterial and left ventricular pressure, which is especially important in patients with mitral regurgitation in whom the amount of regurgitant volume varies in direct relation to the level of the afterload, and (4) the force of contraction of the left ventricular ring during ventricular systole. Considering the principal factors that determine the size of the V wave and the pressure in the pulmonary venous-left atrial system, we can explain why some patients without mitral regurgitation have a large V wave and also why some patients with severe mitral regurgitation may have normal left atrial pressure and a normal V wave.[36]

Clinical implications: As flow-directed catheters for hemodynamic monitoring have become widely available[37,38] and because the central venous pressure has been discarded as an appropriate index of left ventricular filling pressure in patients with acute myocardial infarction or other severe medical or surgical conditions,[3,4] an increasing number of patients undergo right heart catheterization during their stay in an intensive care unit.[1,2] The presence of a large V wave in the pulmonary wedge pressure is usually interpreted as representing mitral regurgitation,[5,6] and therapy may be modified accordingly. Awareness of the findings of our study, that is, that a large V wave may not be associated with mitral regurgitation, seems most important among physicians performing hemodynamic monitoring of patients in critical condition. The data in our study demonstrate that the size of the V wave or the mean pulmonary wedge pressure ratio is not useful in predicting the presence or absence of mitral regurgitation. An exception to this concept are patients with acute mitral regurgitation, known to have giant V waves.[39] Determining the slope of ascent of the V wave, a measurement not always possible in bedside hemodynamic monitoring, is a more sensitive and specific test in the diagnosis of mitral regurgitation. Our findings are also relevant in the interpretation of data obtained in the catheterization laboratory, especially in cases in which the diagnosis of mitral regurgitation is in question or in cases in which left ventriculography is not definite or diagnostic for the presence or absence of mitral regurgitation.

Limitations of the Study

Angiographic determination of mitral regurgitation: Selective angiography is the procedure of choice for evaluating the competence of the mitral valve.[40] As long as the ventricle is well opacified, any amount of mitral regurgitation will be detected. The problems with left ventriculography are creation of artifactual mitral regurgitation due to premature beats or catheter malposition and quantification of the mitral regurgitation.[41] These possible pitfalls of left ventriculography should not alter the conclusions and clinical implications of our study.

Study population: All patients in our study were referred for diagnostic cardiac catheterization and angiography. They may not be representative of the population undergoing right heart catheterization in intensive care units, in which case the proportion of patients with a large V wave and no mitral regurgitation may be different. Our analysis of the hemodynamic factors related to the high V wave should remain valid.

Pulmonary wedge pressure may not reflect exactly the changes in pressure occurring in the left atrium: A close relation between pulmonary wedge and left atrial pressure was demonstrated many years ago.[42,43] Minimal differences in peak, minimal, and mean pressure (averaging less than 1 mm Hg) are common,[44] but larger differences (pulmonary wedge pressure 35% higher than left atrial pressure) have been reported.[45] A phase delay in pulmonary wedge pressure is produced by the distance between the pulmonary vessel containing the wedge catheter and the left atrium. We previously demonstrated by simultaneous recording of pulmonary wedge and left atrial pressure (unpublished data) that some patients have a relative damping of the pulmonary wedge pressure tracing, especially in the slope of the Y descent; this damping effect does not suppress the cyclical changes in left atrial pressure, especially when the latter is elevated above normal.[46]

Direct left atrial pressure recording could have allowed better analysis of the morphology of the V wave and its relation to other hemodynamic variables. This remains to be studied. The major finding in our study, that is, that large V waves can occur in the absence of mitral regurgitation, should not be altered by these considerations.

Pregnancy in Patients With a Porcine Valve Bioprosthesis

UBERTO BORTOLOTTI, MD,* ALDO MILANO, MD,* ALESSANDRO MAZZUCCO, MD,* CARLO VALFRE, MD,* ROSARIO RUSSO, MD,† MARIALUISA VALENTE, MD,‡ LUCIANO SCHIVAZAPPA, MD,† GAETANO THIENE, MD,‡ and VINCENZO GALLUCCI, MD†

Seven patients who became pregnant after valve replacement with a Hancock bioprosthesis were followed up during 8 pregnancies. Six had undergone isolated mitral valve replacement, and 1 had mitral and aortic valve replacement. Their age at the time of operation ranged from 14 to 31 years (average 24); delivery occurred 21 to 88 months (average 51.3) after valve replacement. All women were in sinus rhythm at the time of gestation, and administration of oral anticoagulants was avoided in all. No embolic episodes occurred either after operation or during pregnancy, labor, or puerperium. The only major complication during pregnancy was cardiac failure in 1 patient, associated with onset of atrial fibrillation.

Four women had vaginal delivery and 3 required cesarean section. All but 1 delivered a normal, healthy baby. One premature infant died soon after birth because of respiratory distress. No maternal or fetal hemorrhagic complications were observed.

One patient died 3 months after delivery in severe heart failure caused by diffuse calcification of both mitral and aortic xenografts. Another woman underwent successful reoperation soon after the second pregnancy because of calcific stenosis of the mitral porcine valve.

It is concluded that (1) bioprosthetic valves can be considered the most suitable devices employed in women of childbearing age because anticoagulants can be avoided, therefore eliminating the risks related to inappropriate administration of oral anticoagulants as well as the hazards associated with the potential teratogenic effect of coumarin drugs; and (2) pregnancy might favor calcification of porcine heterografts, leading to bioprosthetic failure. Until further data are available to support this suspicion, close clinical and echocardiographic follow-up study of these patients is recommended after pregnancy.

Pregnancy may be hazardous in patients with a mechanical prosthesis because administration of an oral anticoagulant may be harmful to the fetus whereas suspension of such treatment exposes the mother to an undue risk of embolic complications.[1-5] For this reason, the use of porcine bioprostheses is recommended in young women of childbearing age. However, little information is currently available on the clinical course of patients who become pregnant after heart valve replacement with a porcine xenograft. We present our experience in a series of 7 such patients.

Methods

Patients: Seven women who had previously undergone cardiac valve replacement employing 1 or more glutaraldehyde-preserved Hancock bioprostheses (Hancock Laboratories Anaheim, California) subsequently became pregnant. Their ages ranged from 14 to 31 years at the time of operation (mean 24). Six received isolated mitral valve replacement and 1 received combined mitral and aortic valve replacement. Indications for surgery were rheumatic endocarditis in 6 and congenital mitral insufficiency in 1. All patients were maintained postoperatively on a regimen of digoxin, which was combined with diuretic therapy in 3. An oral anticoagulant (sodium warfarin) was administered in all until the third postoperative month and discontinued thereafter.

Pregnancy and labor: All patients were accurately followed up during pregnancy and hospitalized at least 3 weeks before the expected time of delivery. During labor and delivery, maternal and fetal heart rates, maternal blood pressure, and central venous pressure were continuously monitored.

TABLE I Summary of Clinical and Follow-Up Data

Case	Age (yr) at PVR	Operation	Prepartum NYHA Class and Rhythm	Interval From PVR to Delivery (mo)	Anticoagulation During Pregnancy	Other Medications During Pregnancy	Type of Delivery	Complications During Pregnancy	Follow-up Data
1	18	MVR	1, SR	72	None	Digoxin	Cesarean, at term	AF, 6th mo	Functional Class 3, AF, 11 yr 2 mo postoperatively
2	25	MVR	1, SR	88	None	Digoxin	Cesarean, at term	Threatened to abort, 11th wk	Functional Class 1, SR, 9 yr 10 mo postoperatively
3*	14	MVR	1, SR	48	None	Digoxin	Vaginal, at term	None	
			2, AF	84	Calcium heparin	Digoxin, diuretics	Vaginal, premature	Cardiac failure, AF, 7th mo	Reoperated for calcific stenosis of mitral bioprosthesis during puerperium; functional Class 1, AF, 1 yr after reoperation
4	24	MVR	1, SR	21	None	Digoxin	Vaginal, at term	None	Functional Class 2, SR, 8 yr postoperatively
5	31	MVR	1, SR	42	None	Digoxin	Vaginal, at term	None	Functional Class 1, SR, 6 yr 2 mo postoperatively
6	30	MVR	1, SR	33	None	Digoxin, dipyridamole	Cesarean, 8th mo	Threatened to abort, 11th wk	Functional Class 1, SR, 5 yr 9 mo postoperatively
7	28	AVR, MVR	2, SR	23	None	Digoxin, diuretics	Vaginal, at term	None	Died from cardiac failure 2 mo after delivery; at necropsy, calcific stenosis of both bioprostheses

* This patient had 2 pregnancies.
AF = atrial fibrillation; AVR = aortic valve replacement; MVR = mitral valve replacement; NYHA = New York Heart Association functional class; PVR = prosthetic valve replacement; SR = sinus rhythm.

During the first week of the puerperium, electrocardiograms were taken frequently. All patients received prophylactic wide-spectrum antibiotics during labor and for the first 5 postpartum days.

Results

Clinical data (Table I): The 7 women were followed up during 8 pregnancies, at which time their ages ranged from 18 to 35 years (mean 28); the interval between valve replacement and delivery averaged 51.3 months (minimum 21, maximum 88).

All women were in sinus rhythm at the onset of pregnancy; 6 were in functional class I (New York Heart Association criteria) and 1 was in class II. In 1 patient (Case 1) atrial fibrillation developed during the 6th month of gestation; another (Case 3), who was in sinus rhythm and in class I at the time of her first pregnancy, changed to class II when she became pregnant for the second time; during the seventh month of her second gestation atrial fibrillation developed.

Medications administered during pregnancy included digoxin in all cases, occasionally associated with diuretics, and antiplatelet drugs in 1. No anticoagulants were given, except in 1 patient (Case 3) who received low dose calcium heparin subcutaneously starting at the 32nd week of her second pregnancy, when she was hospitalized because of the onset of cardiac failure and atrial fibrillation.

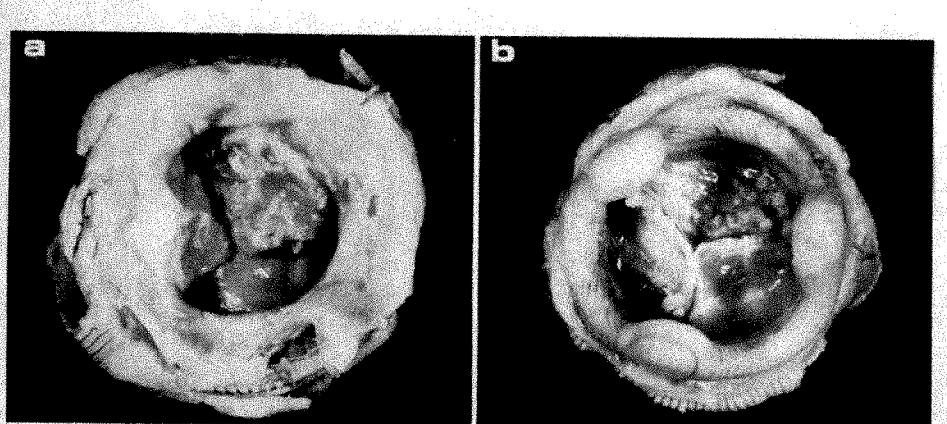

FIGURE 1. Case 3. Gross appearance of the explanted mitral porcine bioprosthesis. The device was recovered at reoperation performed for severe prosthetic stenosis. **a,** atrial view showing fibrocalcific tissue overgrowth partly covering the surface of the cusps. **b,** ventricular aspect of the same device demonstrating the calcific infiltration of cusps and commissures, with severe stiffness and stenosis of the xenograft.

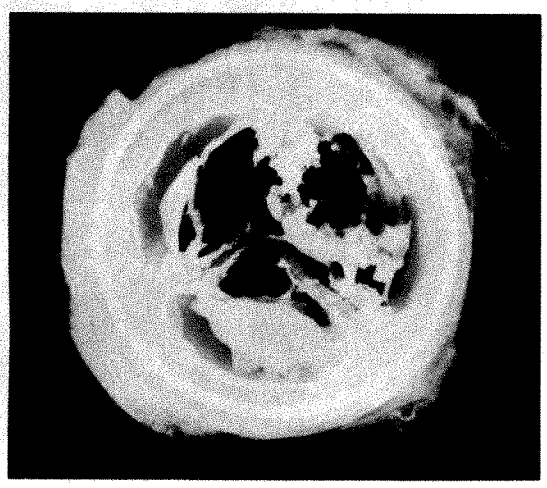

FIGURE 2. Case 3. X-ray examination of the same explant showing coarse calcific deposits in all cusps and commissures.

All pregnancies but 1 were carried out successfully. Four patients had a vaginal delivery; 3 of them gave birth at term to a healthy baby. One (Case 3) delivered for the 1st time a normal baby at term, whereas at the eighth month of her second pregnancy she delivered a premature infant with severe respiratory distress who died shortly thereafter.

Three women had a cesarean delivery based on obstetric indications, performed under general anesthesia. No significant variations in the fetal heart rate and no excessive blood loss occurred in any patient, regardless of the type of delivery.

Complications during pregnancy, labor, and puerperium: In 2 patients (Cases 2 and 6) the possibility of a spontaneous abortion arose around the 11th week of gestation; both were successfully managed. One patient (Case 3) had evidence of congestive heart failure during the second pregnancy, coincident with the onset of atrial fibrillation; she was managed with digitalis, diuretics, and calcium heparin.

Labor was well tolerated in all cases. Complications during puerperium were observed only in Patient 3. The persistence of heart failure in this case, despite vigorous medical treatment, prompted a hemodynamic investigation which revealed severe stenosis of the mitral valve bioprosthesis. This patient was successfully reoperated on shortly after delivery; at surgery the mitral porcine valve appeared grossly calcified and stenotic and was replaced with a mechanical prosthesis (Fig. 1). Both x-ray (Fig. 2) and ultrastructural (Fig. 3) investigations confirmed the presence of calcific deposits in the cusps tissue. No systemic embolic episodes occurred during pregnancy, labor, or puerperium.

Late results and follow-up: In 1 patient (Case 7) severe heart failure developed 3 months after delivery. She was erroneously considered at another institution to have cardiomyopathy and eventually died despite medical treatment. Necropsy revealed that both the aortic and mitral xenografts were highly calcified and stenotic, with thrombosis of the cusp sinuses; death was therefore ascribed to bioprosthesis dysfunction.

FIGURE 3. Case 3. Transmission electron micrograph of 1 cusp of the same device. Within the cytoplasm of a native pig cell calcification is present, resulting from the concentric deposition of hydroxyapatite crystals. The collagen bundles, surrounded by interstitial edema, are still fairly preserved. (Uranyl acetate and lead cytrate; original magnification ×18,000, reduced 44%.)

Five patients are currently alive approximately 6 to 11 years after operation and 1 to 6 years after pregnancy; the sole woman who was reoperated on is asymptomatic 1 year after prosthetic valve replacement. Four patients are still in sinus rhythm and 2 in atrial fibrillation; only 1 of the latter is receiving an oral anticoagulant. Four women are in functional class I, 1 is in class II, and 1 in class III. This patient (Case 1) is the only one to have undergone control cardiac catheterization, which demonstrated stenosis of the mitral valve bioprosthesis; she is presently awaiting reoperation. In 2 other cases an echocardiographic investigation recently performed showed that the porcine valve appears to function properly in both patients. Finally, in 1 case (Patient 4) dysfunction of the mitral xenograft is suspected on clinical grounds because of an apical systolic regurgitant murmur.

Discussion

Advantages of bioprosthesis valve in pregnant women: Women of childbearing age with valvular heart disease may represent a difficult problem for the sur-

geon to whom they are referred for prosthetic valve replacement. Various groups have reported their experience with mechanical prostheses in pregnant patients and the numerous complications related to the use of anticoagulants in such cases.[1–4,6–9] Oral anticoagulants of the warfarin type may be dangerous for the fetus because they cross the placental barrier and may cause fetal hemorrhage and malformation.[5,10–13] Moreover, the mother may be exposed to the risk related to either excessive or reduced anticoagulation, which may threaten both her life and the survival of the fetus.[1–3] As a consequence, gestation in women with a mechanical prosthesis, although feasible, is very hazardous; therefore, extreme care in the use of anticoagulants as well as accurate cardiovascular management is considered a prerequisite of successful pregnancy in such patients.[7]

Porcine bioprostheses have been advocated in young women of childbearing age,[2] because problems and hazards related to anticoagulant treatment, which may be avoided in most patients receiving such devices, are considerably reduced. However, little is known about the course of pregnancy in patients with a porcine heterograft. Our experience underlines that women who become pregnant after prosthetic valve replacement with a porcine bioprosthesis may successfully carry on their pregnancy without significant prosthesis-related complications.

The hypercoagulability state occurring during pregnancy[14,15] usually increases the need for anticoagulant therapy in patients with an artificial valve. In the present series, no oral anticoagulants were administered throughout pregnancy, labor, or puerperium, and no systemic embolic episodes were noted. This good result may probably have been favored by the fact that all women were in sinus rhythm; nevertheless, the absence of embolic complications is relevant.

The circulatory overload which occurs in pregnancy may be poorly tolerated by women with obstruction of the left atrial outflow, resulting in severe pulmonary congestion.[14–16] We have observed this complication only once; indeed, this patient required reoperation shortly after delivery because of severe stenosis of a mitral bioprosthesis. The dysfunction of the xenograft likely contributed to the onset of congestive heart failure.

Porcine valve calcification: relation to pregnancy: We were highly impressed by the severe calcification of the porcine heterograft implanted in 2 patients of this series. One underwent successful reoperation whereas the second died from heart failure before reoperation could be performed. This experience led us to suspect that pregnancy might favor calcification of the porcine xenograft, although the possible mechanisms remain unclear. The level of serum calcium is usually normal or slightly depressed during pregnancy[17]; however, an increased turnover of calcium could occur in the mother in order to fulfill the requirements of the growing fetal skeleton. Calcium, most likely derived from the mother's bones, could partly be deposited on foreign biologic tissue, such as the porcine valve cusps. One must consider, however, that in 1 of our patients (Case 3), dysfunction of the mitral bioprosthesis became apparent after her second pregnancy and that the same patient was an adolescent at the time of valve replacement; indeed, calcification of porcine heterografts implanted in young subjects has been reported repeatedly.[18–20]

Implications: Further data are needed to confirm whether a relation exists between pregnancy and calcification of porcine valves. In the meantime, a closer cardiologic follow-up study of such patients, possibly associated with periodic echocardiographic evaluation, appears advisable after delivery in order to detect early signs of bioprosthetic dysfunction. Our current policy in dealing with young women who need a prosthetic valve and who desire to carry on a pregnancy after valve replacement is to explain to them that having the valve replaced with a biologic prosthesis is the simplest and safest way to have a child, because with such a device complications during pregnancy are minimized. However, reoperation for bioprosthetic failure might be needed earlier than expected.

According to our results, pregnancy in patients with a porcine bioprosthesis is well tolerated and successfully carried out in most cases. The absence of embolic episodes in this series, despite the lack of anticoagulant treatment and the hypercoagulability state of pregnancy, suggests that bioprostheses are currently the most suitable devices for use in women of childbearing age.

They only taste the water.

In potassium therapy
patient compliance is not the only advantage with KAON CL-10... it provides all the benefits of 8 mEq wax-matrix tablets for patients who can't or won't take liquid supplements... PLUS simplified dosage.

10 mEq strength permits fewer tablets, fewer doses per day.

10 mEq strength provides 25% more KCl with no increase in cost.

10 mEq strength encourages compliance because of a more convenient dosage schedule.

10 mEq KCl strength is more easily adjusted to multiples of 10.

It's time for a change to

KAON CL-10™

(potassium chloride)
10mEq controlled release tablets

ADRIA LABORATORIES INC., Columbus, Ohio 43215
Please turn page for brief summary of prescribing information.

KAON CL-10 (potassium chloride) 10 mEq Controlled Release Tablets

Description: Kaon Cl™-10 mEq is a sugar coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy; and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon Cl™-10 mEq (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon Cl-10 mEq should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:
Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
Correction of acidosis, if present, with intravenous sodium bicarbonate.
Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100 and 500; Stat-Pak® (Unit-Dose) box of 100.

ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

To reduce the risk of potentially fatal arrhythmias in such patients

QUINAGLUTE® 324 mg DURA-TABS®

(quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

QUINAGLUTE® (quinidine gluconate) DURA-TABS®
INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.
Drug Interactions:

Drug	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.
See package insert for full information.

PHARMACEUTICAL DIVISION

When technology advances so fast it puts 10-year olds in museums

...you need the Medtronic difference.

Only a decade ago pacemaker technology was led by the Medtronic Chardack™ Model 5910 "programmable" pacemaker. First implanted in the United States in 1972, the unit was programmed invasively, percutaneously introducing a Keith surgical needle into a potentiometer to adjust rate. A cumbersome technique, but the best available then.

However this technology brought a new capability to physicians to restore a more vital life to their patients. *It was technology not for its own sake, but for the patient's sake.* That's part of the Medtronic Difference.

Today we offer you programming options with precise electronic telemetry encapsulated in thin, light titanium housings 72% smaller than units just 10 years ago. These are remarkable programmable pacemakers, each can be noninvasively fine-tuned to alleviate a wide range of cardiac disorders. They can be programmed to meet patient pacing requirements throughout their varying clinical course.

These cost-effective programmable pacing systems, together with Medtronic patient follow-up equipment, make it possible for more patients to resume a full lifestyle. By technologically improving your patient's quality of life with less follow-up required, *the cost of cardiac pacing is steadily decreasing.*

Beyond technology, the Medtronic Difference is having the world's leading pacing company standing behind you. We are ready to assist you in your patient management needs with all our resources.

Medtronic Implantable Pulse Generators and Leads

Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

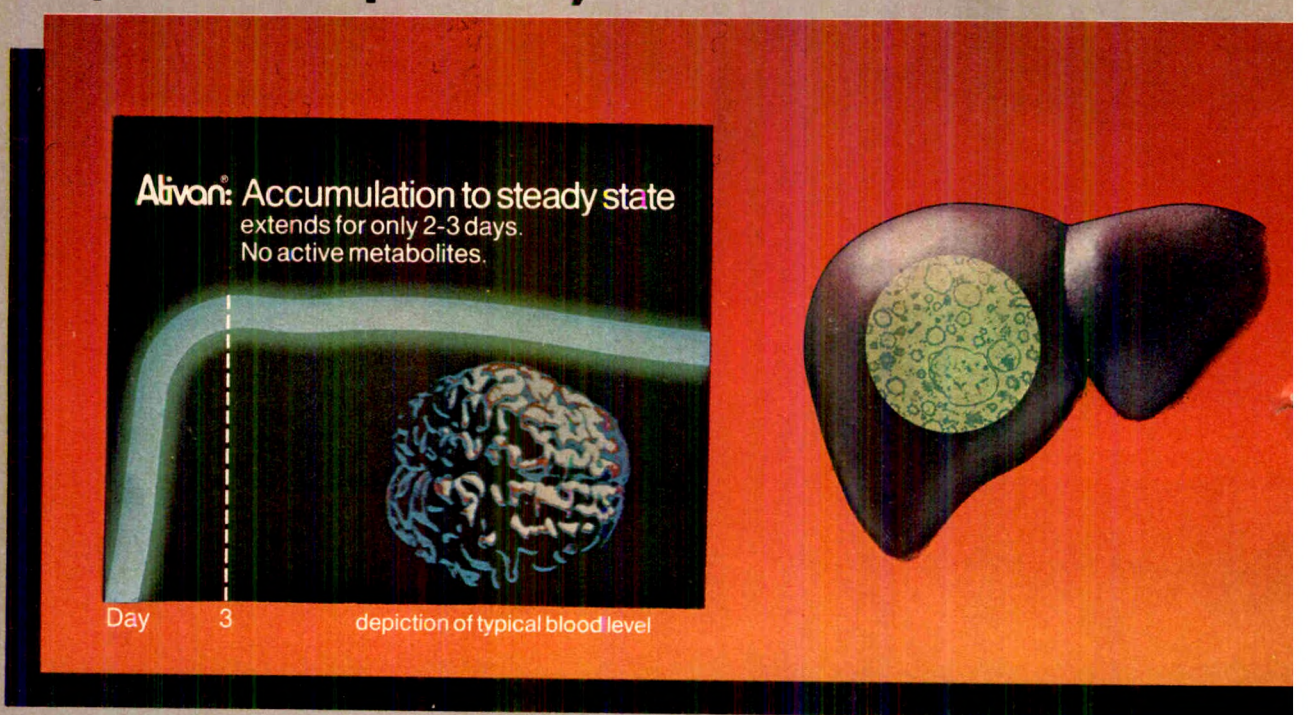
Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Ativan®: Agent
(lorazepam)



because...

it's shorter acting, with brief accumulation

In contrast to long-acting benzodiazepines, Ativan has a short, 12-hour half-life, and no active metabolites. In multiple-dose therapy, Ativan accumulates for only 2 to 3 days before reaching steady state; the long-acting benzodiazepines—diazepam CIV, chlordiazepoxide CIV, clorazepate CIV and prazepam CIV—with their active metabolites accumulate for as long as 20 days before reaching steady state. Cumulative sedative effects are seldom a problem with Ativan.[1]

it doesn't interact with drugs metabolized by P450 microsomal enzymes

Most benzodiazepines undergo oxidative metabolism and thus utilize the hepatic microsomal enzyme system. Ativan® (lorazepam), however, is metabolized by glucuronidation and does not compete with other drugs for cytochrome P450. Thus, when Ativan is given with Tagamet® (cimetidine), for example, clearance is not delayed, nor sedation increased*—unlike reported observations with patients on other benzodiazepines.[2-6]

# of Change

it gives you greater control of therapy

The short half-life of Ativan® (lorazepam) facilitates more rapid response to dosage adjustments, allowing you to titrate therapy to patients' changing needs. Also, once you decide to discontinue Ativan, it will be out of your patient's system 4 days after the final dose—in contrast to long-acting benzodiazepines and their active metabolites which take as much as 2 weeks to be totally eliminated.

Ativan®
for (lorazepam) IV
Anxiety

Wyeth Laboratories
Philadelphia, PA 19101

See important information on following page.

Brief Summary of Prescribing Information

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan®
for (lorazepam) ℞
Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Wyeth Laboratories

CLASSIFIED

CARDIAC REHABILITATION FELLOWSHIP

3rd year academic cardiac rehabilitation fellowship for 8-month rotation through cardiac rehab/clinical research rotation, 4-month rotation through other non-invasive/invasive sections in Division of Cardiology. Opening available for July 1, 1983. Contact:

St. Louis University
Medical Center

Cardiac Rehabilitation Program
1325 South Grand Boulevard
St. Louis, Missouri 63104
314-771-7600, extension 3630

An EEO Handicap Employer M/F-AA

HOUSTON—POSITION AVAILABLE FOR BOARD CERTIFIED OR ELIGIBLE CARDIOLOGIST. Accredited 67-physician internal medicine group. For further information, send Curriculum Vitae to Administrator, Diagnostic Clinic of Houston, 6448 Fannin, Houston, Texas 77030.

HAMAD GENERAL HOSPITAL, a new 660 bed referral facility, invites applications from Board Certified Clinicians in:

Cardiology—Adult and Paediatric

Salaries are highly competitive and commensurate to clinical and academic experience. Contracts are for a three-year period.

Benefits include free accommodation, utilities, air tickets to and from Doha for a family of 5 (Dependent children to age 19), 60 days paid vacation, generous excess baggage allowances, Educational allowances and no Qatari income tax.

Please send complete Curriculum Vitae to: THE MEDICAL DIRECTOR, HAMAD GENERAL HOSPITAL, P.O. Box 3050, Doha, Qatar, Arabian Gulf.

CARDIOLOGIST

Board eligible or certified to share a hospital based practice with two other cardiologists. Our new associate will join a growing practice involving invasive and non-invasive cardiology, consulting, and work in a newly constructed C.C.U. The successful candidate will practice at a progressive mid-western hospital affiliated with a state school of medicine. Please reply with curriculum vitae to: Box 230, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CARDIOLOGIST WANTED—Large Midwest Multi-Specialty Group has an immediate opening in Cardiology. Excellent income and benefit schedule. Contact Kenneth L. Day, M. D., Wausau Medical Center, S. C., 2727 Plaza Drive, Wausau, Wisconsin 54401 or call collect (715) 847-3351.

Electrophysiologic Drug Testing in Patients With Malignant Ventricular Arrhythmias: Importance of Stimulation At More Than One Ventricular Site

FRED MORADY, MD, DAVID HESS, MD, and MELVIN M. SCHEINMAN, MD

Sixty-four patients with symptomatic ventricular tachycardia or ventricular fibrillation underwent right ventricular apical programmed stimulation and had no inducible ventricular tachycardia during drug testing. Thirty patients (Group I) did not undergo left ventricular stimulation. Left ventricular stimulation in 38 drug trials induced no ventricular tachycardia in 50% (Group IIA), nonsustained ventricular tachycardia in 26% (Group IIB), and sustained ventricular tachycardia in 24% (Group IIC).

Patients in Groups I, IIA, and IIB received chronic antiarrhythmic drug therapy based on the results of electrophysiologic drug testing. Patients in Group IIC underwent further drug testing until sustained ventricular tachycardia was no longer inducible and were then entered into Group IIA or IIB; 4 patients in whom the induction of sustained ventricular tachycardia could not be suppressed by any drug regimen tested were excluded from long-term follow-up. The duration of follow-up (mean ± standard deviation) was 15.8 ± 11.5 months in Group I, 13.6 ± 3.7 months in Group IIA, and 12.1 ± 4.9 months in Group IIB. Recurrence rates of symptomatic ventricular tachycardia or sudden death were 27% in Group I, 0% in Group IIA, and 20% in Group IIB ($p < 0.02$ for Group IIA versus Group I and $p > 0.05$ versus Group IIB).

If only right ventricular apical stimulation is performed during electrophysiologic drug testing in patients with malignant ventricular arrhythmias, approximately 50% of drug trials may be incorrectly judged as suppressing the induction of ventricular tachycardia. Drug therapy that suppresses ventricular tachycardia induction with both right and left ventricular programmed stimulation results in a significantly better clinical response than therapy based on the results of only right ventricular apical stimulation.

Programmed ventricular stimulation has been demonstrated to result in the induction of ventricular tachycardia (VT) in 80 to 90% of patients who have had recurrent VT.[1-4] Furthermore, drug testing during programmed ventricular stimulation has been shown useful in predicting the long-term efficacy and inefficacy of antiarrhythmic drugs in preventing recurrent malignant ventricular arrhythmias.[1,3,5-7] Nevertheless, despite long-term treatment with drugs demonstrated to prevent the laboratory induction of VT, up to 32% of patients have been reported to have recurrence of VT over an 18 month follow-up period.[6]

Previous studies[1-4,8] of patients with documented VT revealed that programmed stimulation at multiple right ventricular sites or with multiple pacing rates, or both, results in the induction of VT in approximately 85 to 90% of patients. We found similar results in a consecutive series of 40 patients with spontaneous VT using a single right ventricular site (apex) and a single basic drive rate (500 ms) and triple extrastimuli. Thirty-five of these 40 patients (88%) had inducible VT. The proximity of the stimulation site to a potential reentry circuit is an important factor in the induction of a reentrant arrhythmia.[9,10] Because most adult patients with recurrent VT have coronary artery disease and VT that originates in the left ventricle,[11] it is possible that during drug testing some patients might have VT that

From the Department of Medicine, University of California, San Francisco, California. Manuscript received March 9, 1982; revised manuscript received April 12, 1982, accepted May 26, 1982.

can be induced with left but not right ventricular stimulation. If so, then programmed stimulation of the right ventricular apex alone might be an inadequate test of drug efficacy in suppressing VT induction.

Because our pilot studies showed that stimulation of the right ventricular apex with 3 extrastimuli induced VT in a similar percentage of patients as did more aggressive right ventricular stimulation protocols, we chose to assess the value of left ventricular programmed stimulation during drug testing in patients with malignant ventricular arrhythmias. Two main questions have been addressed with regard to electrophysiologic drug testing: (1) In patients in whom VT cannot be induced with right ventricular apical stimulation, how often will left ventricular programmed stimulation result in VT induction? (2) Is drug testing based on programmed stimulation of more than 1 ventricular site a better predictor of long-term clinical response than drug testing based on right ventricular apical stimulation alone?

Methods

Sixty-four patients with symptomatic VT or ventricular fibrillation (VF) form the basis of this report. In 40 patients, VT was documented in association with symptoms of syncope, presyncope, or palpitations either with a 24 hour ambulatory electrocardiographic recording or by an electrocardiogram obtained in the hospital or by paramedics. In 24 patients who had cardiac arrest, VF was documented before direct-current cardioversion. Patients with evidence of myocardial infarction within 4 weeks of the most recent episode of VT or VF were excluded as were patients with VT or VF due to metabolic disturbances such as severe hypokalemia. In addition, patients with the long Q-T syndrome were excluded based on a previous study demonstrating that programmed ventricular stimulation is of limited value in patients with this syndrome (Morady F et al., unpublished observations). Left ventricular ejection fraction was assessed either by left ventricular angiography at the time of cardiac catheterization or with a technetium-99m radionuclide angiogram.

Thirty patients (Group I) underwent only right ventricular apical programmed stimulation during drug testing and were found to have no inducible VT. Twenty-six of these patients were studied before initiation of a left ventricular stimulation protocol in our laboratory in January 1980. In the remaining 4 patients, left ventricular stimulation was not performed either because of a prosthetic aortic valve or marked tortuosity of the aorta or iliac arteries, preventing the retrograde passage of a electrode catheter across the aortic valve.

Thirty-four patients (Group II) who had no inducible VT with right ventricular apical stimulation during drug testing then underwent left ventricular programmed stimulation during the same study.

Electrophysiology study protocol: After obtaining informed consent, ventricular stimulation studies were performed in the fasting, unsedated state. A quadripolar electrode catheter was inserted percutaneously through a femoral vein and positioned against the apex of the right ventricle. A second catheter was positioned across the tricuspid valve for recording the His bundle electrogram. A short polyethylene catheter was inserted into a femoral artery for monitoring arterial blood pressure. For left ventricular stimulation, a bipolar electrode catheter was inserted percutaneously into a femoral artery and positioned against the apex of the left ventricle. Patients underwent systemic heparinization during left ventricular stimulation. Electrocardiographic leads V_1, I, and III and intracardiac electrograms were recorded using a VR-12 Electronics for Medicine recorder. Ventricular stimulation was performed with pulses 2 ms in duration, delivered at a constant current of 2 to 3 times the diastolic threshold by a programmable stimulator (Bloom).

The following ventricular stimulation protocol was used in all patients. Ventricular drive was instituted at a cycle length (S_1-S_1) of 500 ms and a single extrastimulus (S_2) was inserted 450 ms after the last driven complex and moved progressively closer to S_1, by 10 ms decrements, until the ventricular effective refractory period (VERP) was reached. The VERP was defined as the longest S_1-S_2 interval that did not evoke a ventricular response. If sustained VT was not induced, S_2 was positioned 30 ms outside the VERP and a second extrastimulus (S_3) was inserted and moved progressively closer to S_2 until ventricular refractoriness was reached. The S_3 was positioned 30 ms outside the point of refractoriness and a third extrastimulus (S_4) was then inserted and moved in by 10 ms decrements. If VT was not induced, S_2 and S_3 were moved progressively closer to S_1 and diastole was again scanned with S_4. Short bursts of overdrive pacing were then performed at cycle lengths of 600 to 300 ms. The same stimulation protocol was performed in both the right and left ventricles.

Sustained VT was defined as VT at least 30 seconds in duration or requiring direct-current cardioversion or overdrive pacing for termination. Nonsustained VT was defined as VT of 6 beats to 30 seconds in duration.

Drug testing protocol: In Group I, 26 of 30 patients underwent their initial study while being treated with 1 or more antiarrhythmic drugs. In 15 of the 30 patients, VT was induced during the initial drug trial, and further drug testing was performed until VT could no longer be induced with right ventricular apical stimulation.

In Group II, 20 of 34 patients underwent initial study while receiving antiarrhythmic drug therapy. Ventricular tachycardia was induced with right ventricular programmed stimulation during the initial study in 26 patients. These patients underwent further drug testing until VT could no longer be induced with right ventricular stimulation, and then they underwent left ventricular stimulation. Antiarrhythmic drugs were administered at the time of initial study in an attempt to prevent VT induction and minimize the need for direct-current cardioversion.

Drugs were tested based on each patient's history of drug intolerance and previous clinical response. The following oral agents were tested during the last 1 to 2 hours of the dosing interval, after administration of a sufficient number of doses to attain a steady-state serum drug level: procainamide, 3 to 8 g/day; quinidine, 1.2 to 1.6 g/day; disopyramide, 400 to 600 mg/day; propranolol, 160 to 480 mg/day; tocainide, 0.8 to 1.2 g/day; and dilantin, 300 mg/day. Because of its extended half-life, amiodarone, 600 to 800 mg/day, was tested 2 to 3 months after initiation of therapy. The following drugs were tested acutely in the laboratory after intravenous administration: procainamide, 750 to 1,500 mg; propranolol, 0.15 mg/kg; lidocaine, loading dose of 225 mg over 20 minutes, concomitant with a 2 mg/min continuous infusion.

Serum drug levels (procainamide, quinidine, propranolol, dilantin, or tocainide but not disopyramide, nadolol, or amiodarone) were measured after right ventricular stimulation in all Group I patients. In Group II, serum drug levels were measured after right ventricular stimulation in 21 of 38 drug trials and after left ventricular stimulation in all.

Chronic drug therapy and follow-up: Chronic drug therapy was adjusted to yield serum drug levels that matched drug levels tested in the laboratory. Group I patients were treated chronically with agents that prevented VT induction by right ventricular apical stimulation (Table I).

Based on the results of left ventricular stimulation, Group II patients were divided into 3 groups:

Group IIA consisted of patients in whom no VT was inducible with left ventricular programmed stimulation. These patients were treated chronically with agents found to prevent VT induction in the laboratory (Table I).

Group IIB consisted of patients in whom nonsustained VT was inducible with left ventricular stimulation. One of these patients underwent coronary artery bypass grafting with map-directed endocardial resection and was excluded from chronic follow-up. The remainder of patients in this group were treated chronically with agents that were tested in the laboratory and found to prevent induction of sustained but not unsustained VT (Table I).

Group IIC contained the patients in whom sustained VT was inducible. These patients underwent further drug testing. If sustained VT could no longer be induced, they were then assigned to Group IIA or IIB. In 4 patients, the induction of sustained VT could not be suppressed by any drug regimen tested; these patients were excluded from long-term follow-up in this study. (They were treated with amiodarone and have had no recurrence of symptomatic VT over 12 to 18 months.)

Patients were followed on a regular basis by either 1 of the authors or by the patient's referring physician. Twenty-four hour ambulatory electrocardiographic recordings were obtained every 3 to 4 months. Referring physicians were questioned periodically regarding changes in drug therapy and recurrence of symptoms. Patients were excluded from further follow-up if and when there was a change in drug therapy. Sudden death was defined as unexpected death within 1 hour of the patient's collapse.

Statistical analysis: Values are expressed as mean ± standard deviation. Statistical analysis were performed either with Fisher's exact test or unpaired Student's t test. A paired t test was used to compare serum procainamide or quinidine levels measured immediately after right and left ventricular stimulation in Group II patients.

Results

Patient characteristics: Patients in Group I had 4.0 ± 5.2 episodes of symptomatic VT or VF over 9.9 ± 13.5 months before inclusion in this study. Patients in Group II had 6.6 ± 7.6 episodes of symptomatic VT or VF over 10.9 ± 20.3 months. There was no significant difference between the 2 groups either in the number of episodes of VT or VF or in the duration of symptoms ($p > 0.05$). A similar proportion of patients in Groups I and II, 10 of 30 (33%) and 14 of 34 (41%), respectively, had had at least 1 episode of VF ($p > 0.05$).

There was no significant difference between patients in Groups I and II in regard to age, sex ratio, prevalence of underlying heart disease, left ventricular ejection fraction, percentage of patients with previous myocardial infarction, and percentage of patients with congestive heart failure ($p > 0.05$, Table II).

Results of left ventricular programmed stimulation: In 38 drug trials in which VT could not be induced with programmed stimulation of the right ventricular apex, left ventricular stimulation yielded the following results: (1) no induction of VT in 19 (50%); (2) induction of nonsustained (but not sustained) VT in 10 (26%); and (3) induction of sustained VT in 9 (24%). No complications were encountered as a result of left ventricular programmed stimulation.

Ventricular effective refractory periods: There was no significant difference between the right and left VERP either within or between Groups IIA, IIB, or IIC (Table III).

TABLE III Ventricular Effective Refractory Periods in Patients Undergoing Right and Left Ventricular Stimulation During Drug Testing*

Group	Results of LV PS	Right VERP (ms)	Left VERP (ms)
IIA	No VT	276 ± 31	277 ± 45
IIB	Nonsustained VT	290 ± 38	275 ± 48
IIC	Sustained VT	293 ± 23	297 ± 32

* Values are expressed as mean ± standard deviation. There were no statistically significant differences between the right and left VERPs either between or within the three groups ($p > 0.05$).

LV PS = left ventricular programmed stimulation; VERP = ventricular effective refractory period; VT = ventricular tachycardia.

TABLE IV Serum Drug Levels Measured Immediately After Right and Left Ventricular Stimulation*

	Group IIA		Group IIB		Group IIC
	Procainamide (9)	Quinidine (3)	Procainamide (3)	Quinidine (2)	Procainamide (4)
RV PS	10.1 ± 5.0	1.7 ± 0.7	14.2 ± 5.1	1.5 ± 0.6	9.2 ± 2.4
LV PS	9.0 ± 4.3	1.5 ± 0.8	13.6 ± 4.5	1.4 ± 0.6	8.6 ± 2.2

* Numbers in parentheses represent the number of drug trials in which drug levels were measured after RV and LV PS. Values are expressed as μg/ml (mean ± standard deviation); there were no statistically significant differences in the serum drug levels measured after right and left ventricular stimulation.

LV = left ventricular; PS = programmed stimulation; RV = right ventricular.

Serum drug levels during programmed ventricular stimulation: There was no significant difference in the serum procainamide or quinidine levels measured immediately after right and left ventricular programmed stimulation in Groups IIA, IIB, or IIC regardless of whether the drugs were tested after oral or intravenous administration (Table IV).

Characteristics of induced ventricular tachycardia: In Group IIB, the mean duration of the induced nonsustained VT was 17 ± 15 beats (range 7 to 48). The mean cycle length of VT was 266 ± 56 ms. The morphology of the induced VT was identical to that of the clinical VT in 5 of 10 cases. In 4 cases the morphology of the clinical VT was unknown, and in 1 case the clinical arrhythmia was VF. VT was induced with 2 left ventricular extrastimuli in 3 patients and with 3 extrastimuli in 7.

In Group IIC, the mean cycle length of the induced sustained VT was 307 ± 72 ms. The morphology of the induced VT was identical to that of the clinical VT in 5 of 9 cases. In 1 case the clinical VT had a right bundle branch block-superior axis configuration, while the induced VT had a right bundle branch block-inferior axis configuration. In 1 case the morphology of the clinical VT was unknown, and in 2 cases the clinical arrhythmia was VF. The method of VT induction consisted of 3 left ventricular extrastimuli in all cases except 1 in which VT was induced with left ventricular overdrive pacing at a cycle length of 300 ms.

Follow-up: In Group I, the overall duration of follow-up was 15.8 ± 11.5 months. Twenty-two of 30 patients (73%) have had no recurrence of symptomatic VT or VF over 20.6 ± 9.4 months. Five patients (17%) had sudden death and 3 (10%) had a nonfatal recurrence of VT at a mean follow-up time of 2.4 ± 2.2 months.

In Group IIA, the mean duration of follow-up has been 13.6 ± 3.7 months. None of the 19 patients has had a recurrence of symptomatic VT or VF. This recurrence rate of zero is significantly lower than the 27% VT/VF recurrence rate in Group I ($p < 0.02$).

In Group IIB, the overall follow-up time was 12.1 ± 4.9 months. Eight of 10 patients (80%) remained free of symptomatic VT or VF. One patient had sudden death at 1 month of follow-up, and 1 had aborted sudden death at 13 months. This 20% recurrence of malignant ventricular arrhythmias was not significantly different from the recurrence rate in either Group I or IIA ($p > 0.05$).

Discussion

This study evaluated the results of left ventricular programmed stimulation in patients who had no inducible VT with right ventricular stimulation during drug testing. Left ventricular stimulation induced nonsustained VT in 26% of drug trials and sustained VT in 24%. Thus, if programmed stimulation of only the right ventricular apex is performed during electrophysiologic drug testing in patients with malignant ventricular arrhythmias, approximately 50% of drug trials may be incorrectly judged as effectively suppressing the induction of VT.

The clinical importance of stimulation at more than 1 ventricular site is demonstrated by comparing the long-term follow-up of patients treated with antiarrhythmic drugs that prevent VT induction with right ventricular versus right and left ventricular stimulation. In this study, 27% of patients who had no inducible VT with right ventricular apical stimulation during drug testing nevertheless had a recurrence of VT or sudden death. In contrast, among patients in whom VT could not be induced with programmed stimulation of either the right or left ventricular apex during drug testing, the recurrence rate of VT and sudden death was zero ($p < 0.02$). The predictive value of left ventricular stimulation in patients who have no inducible VT with programmed stimulation of the right ventricular apex during drug testing is also suggested by the 20% recurrence rate of VT or sudden death in patients who were treated with agents that did not suppress the induction of nonsustained VT with left ventricular stimulation; however, the difference between this recurrence rate and the zero percent recurrence rate in Group IIA patients was not statistically significant.

In previous studies of the predictive value of electrophysiologic drug testing, left ventricular stimulation was performed during drug testing only when stimulation of the left ventricle was required to induce VT before administration of antiarrhythmic drugs.[3,5] Because 89% of patients with clinically documented VT can be induced to have VT with stimulation of the right ven-

tricle,[8] only a small number of patients in previous reports underwent left ventricular stimulation. In the largest published series on the predictive value of electrophysiologic drug testing, only patients who had VT inducible with right ventricular stimulation (pacing site unspecified) were included in the study, and left ventricular stimulation was not performed during drug testing.[6] Over the 18 months of follow-up, malignant ventricular arrhythmias recurred in 32% of 36 patients treated with drugs predicted to be effective. This arrhythmia recurrence rate is similar to the 27% failure rate over 13.9 months in the 30 patients in the present series treated with drugs predicted to be effective on the basis of right ventricular apical stimulation alone. Thus, electrophysiologic drug testing that includes stimulation of only the right ventricular apex may yield suboptimal results.

The induction of VT with left but not right ventricular stimulation in Group IIB and IIC patients was not related to a difference in the right and left VERPs. In addition, serum levels of measurable drugs such as procainamide and quinidine were similar during right and left ventricular stimulation. We postulate that after administration of antiarrhythmic drugs, extrastimuli introduced in the right ventricular apex might no longer reach a potential reentry circuit in the left ventricle due to an intervening area of conduction block; alternatively, after administration of antiarrhythmic drugs, extrastimuli from the right ventricular apex may no longer produce the appropriate temporal relation between unidirectional block and slowed conduction within a potential reentry circuit necessary to initiate VT. However, extrastimuli introduced in the left ventricle, because of closer proximity to the potential reentry circuit, may be able to penetrate the circuit and satisfy the appropriate criteria to induce VT.

Limitations: Our study has several limitations. The assignment of patients to Group I or II was made neither randomly nor concurrently; that is, Group I consists of all patients evaluated before January 1980 plus patients evaluated later in whom left ventricular stimulation was not feasible. However, the clinical characteristics of the patients in Groups I and IIA were similar. In addition, there were no changes in our ventricular stimulation protocol or drug testing protocol since January 1980 other than the addition of left ventricular stimulation. Thus, we do not believe that any significant bias was introduced into the comparison of outcome in Groups I and II.

A second limitation in our study relates to the fact that many Group II patients (57%) were being treated with antiarrhythmic drugs at the time of their initial ventricular stimulation study. Thus, VT was induced with right ventricular apical stimulation in only 46% of Group II patients. However, based on our experience with stimulation of the right ventricle with 3 extrastimuli, we believe that approximately 90% of Group II patients would have had inducible VT if not for treatment with antiarrhythmic drugs during their initial study.

A critical evaluation of the importance of left ventricular programmed stimulation would require a control group of patients treated chronically with agents that prevented VT induction with right but not left ventricular stimulation. However, we did not think it ethical to treat patients chronically with drugs that did not suppress the induction of sustained VT. Thus, the clinical significance of sustained VT induced by left ventricular stimulation during drug testing must be inferred from the higher recurrence rate of VT and sudden death in the Group I patients, who underwent stimulation of only the right ventricular apex. In addition, based on the 20% recurrence rate of VT and sudden death in Group IIB patients, we no longer treat patients chronically with drugs that do not suppress the induction of nonsustained VT with left ventricular programmed stimulation.

An additional limitation in our study is that the maximal duration of follow-up in Group I (35 months) was longer than in Group IIA (22 months). However, because recurrent VT and sudden death in Group I patients occurred at a mean follow-up time of 2.4 ± 2.2 months, we think it is unlikely that the significantly lower recurrence rate of malignant ventricular arrhythmias in Group IIA patients is attributable to the shorter maximum duration of follow-up.

A final potential limitation of our study is that right ventricular stimulation was performed in only 1 location, the apex. We cannot rule out the possibility that stimulation at other right ventricular sites such as the septum or outflow tract would have induced VT during drug testing in our Group II patients and thus precluded the need for left ventricular stimulation. The results of our study should not be construed as necessarily suggesting the need for left ventricular stimulation during drug testing in patients in whom VT cannot be induced from the right ventricle. The importance of our observations is related to the finding that inability to induce ventricular tachycardia from 1 ventricular site after drug testing does not preclude inducibility from other ventricular sites. This finding appears to have important clinical implications.

Conclusions: Despite the foregoing limitations in our study, the following conclusions can be drawn with regard to electrophysiologic drug testing in patients with malignant ventricular arrhythmias: (1) As previously reported,[12] programmed stimulation of the left ventricle can be performed safely. (2) In patients in whom VT cannot be induced with stimulation of the right ventricular apex, left ventricular stimulation results in the induction of sustained VT in approximately 25% and nonsustained also in approximately 25%. (3) Induction of VT with left ventricular stimulation is not related to a difference between right and left ventricular effective refractory periods. (4) Drug therapy that suppresses VT induction with both right and left ventricular stimulation results in a significantly better clinical response than therapy based on stimulation of only the right ventricular apex; thus, during drug testing, stimulation should not be limited to the right ventricular apex, even when VT is inducible from this site in the baseline state. Whether or not stimulation from multiple right ventricular sites will preclude the need for left ventricular stimulation remains to be determined.

Electrophysiologic Study for Ventricular Arrhythmia: Effect on Total and Myocardial-Specific Creatine Kinase Activity

FRANCIS E. MARCHLINSKI, MD, HARVEY L. WAXMAN, MD, LESLIE M. SHAW, PhD, MARILYN D. EZRI, MD, and MARK E. JOSEPHSON, MD*

To determine the potential for myocardial injury during electrophysiologic study for ventricular arrhythmia, total creatine kinase and creatine kinase B-subunit enzyme activity were serially measured after the procedure in 24 patients. During electrophysiologic study 14 of the 24 patients had sustained ventricular tachycardia or fibrillation, 4 patients had nonsustained ventricular tachycardia, and 6 patients had no ventricular arrhythmia induced. Cardioversion was necessary because of hemodynamic collapse in 9 of the 14 patients with sustained ventricular tachycardia or ventricular fibrillation. Coronary heart disease was present in 14 of the 24 patients, in 9 of the 14 with sustained ventricular tachycardia or ventricular fibrillation, and in 7 of the 9 patients requiring cardioversion. Total creatine kinase was modestly elevated (greater than twice baseline or greater than normal, or both) 24 hours after electrophysiologic study in 10 (42%) of the patients. Electrophysiologic study with or without the induction of ventricular tachycardia or ventricular fibrillation was not associated with increased creatine kinase B-subunit activity even in patients with coronary heart disease.

Currently, the management of life-threatening ventricular arrhythmias, particularly those associated with severe ischemic heart disease, may include the use of programmed stimulation of the heart.[1–4] Frequently, sustained ventricular tachycardia or fibrillation induced by programmed stimulation, such as spontaneous arrhythmia, requires emergency cardioversion. To date, the presence and extent of myocardial damage resulting from insertion of the electrode catheter, programmed stimulation, and induction of ventricular arrhythmia have not been evaluated.

In the present study, total creatine kinase and creatine kinase B-subunit activity, using the Merck immunoinhibition technique, were serially measured after electrophysiologic testing in 24 patients undergoing evaluation of ventricular arrhythmia. The study was designed (1) to assess the effects of electrophysiologic study on total creatine kinase activity, and (2) to determine whether myocardial injury, as reflected by creatine kinase B-subunit activity, occurs during programmed stimulation and induction of arrhythmia, particularly in patients with severe coronary heart disease and ventricular arrhythmias resulting in hemodynamic collapse.

Methods

Patients (Table I): The patients included 18 men and 6 women, aged 16 to 84 years (mean 54.4), undergoing electrophysiologic study for evaluation and therapy of documented or suspected ventricular tachyarrhythmia. Fourteen patients had documented sustained ventricular tachycardia or fibrillation which produced life-threatening symptoms or failed to respond to standard antiarrhythmic drug therapy, or both. The remaining 10 patients had electrocardiographic demonstration of complex ventricular ectopic activity and symptoms of dizziness or syncope.

Fourteen of the 24 patients had coronary heart disease, 3 had idiopathic congestive cardiomyopathy, 1 had rheumatic valve disease, and 6 had no evidence of organic heart disease

* Total delivered energy in joules. The number of shocks is indicated in parentheses. † Elevated total CK activity equals greater than the upper reference limits (see text) or greater than twice the baseline value, or both. Peak value is indicated in parentheses in units/liter. ‡ Elevated CK B-subunit activity equals greater than the upper reference limit of 13 U/liter.

AF = atrial fibrillation; ASHD = atherosclerotic heart disease; CCM = congestive; DC = direct current; cardiomyopathy; LVAn = left ventricular aneurysm; NSVT = nonsustained ventricular tachycardia; RHD = rheumatic heart disease; VF = ventricular fibrillation; VT = ventricular tachycardia.

by cardiac catheterization (4 patients) or gated blood pool scan and echocardiogram (2 patients). Cardiac catheterization was performed in 11 of 14 patients with coronary heart disease. Three patients had single vessel disease, and 4 patients had double and triple vessel disease as judged by 70% or greater obstruction.

None of the 24 patients had intramuscular injections, anginal chest pain, cardiac catheterization, or muscle trauma in the 72 hours before or 24 hours after electrophysiologic study.

Electrophysiologic testing: Studies were performed while the patients were in a nonsedated, postabsorptive state. All venous catheters, except 1, were inserted percutaneously at femoral (54 catheters) or antecubital (15 catheters) sites. One venous catheter was inserted through an antecubital cutdown. Left ventricular catheterization, for the purpose of programmed stimulation or activation mapping of sustained tachycardia, was performed in 9 patients using a femoral arterial percutaneous approach.

The stimulation protocol included the introduction of 1 to 3 ventricular extrastimuli after 8 spontaneous or paced beats at multiple cycle lengths. If ventricular tachycardia or fibrillation was not induced by extrastimuli from up to 3 right ventricular sites, rapid ventricular pacing from the right ventricle at cycle lengths of 350 to 250 ms for 15 seconds was performed. In 7 of the 24 patients up to 3 ventricular extrastimuli were introduced from multiple left ventricular sites after right ventricular stimulation failed to induce tachyarrhythmia. In 19 patients programmed atrial stimulation was also performed. Stimulation was performed with a custom-designed programmable stimulator (Bloom Associates, Narberth, Pennsylvania) using 1 ms impulses at twice diastolic threshold. After completion of the electrophysiologic study, catheters were removed in all patients except 1 (Case 6) in whom a size 6 Fr electrode catheter was left in place at the right ventricular apex for serial drug studies.

Electrical countershock was performed when necessary during electrophysiologic testing using a Bectin-Dickenson Electrodyne cardioverter. The electrode paddle size was 8 cm. After liberal application of redux paste, anterior paddles were positioned for cardioversion just to the right of the sternum at the level of the first and second ribs and in the left anterior axillary line. Maximal deliverable energy capacity for the cardioverter is 320 W-s.

Biochemical procedures: Blood samples were obtained at the time of and 4, 8, and 24 hours after the electrophysiologic study from each of the 24 patients. Baseline samples were obtained immediately before catheter insertion in 18 patients and after catheter insertion in 6 patients. To avoid the possibility of missing small peaks in the total creatine kinase or creatine kinase B-subunit activity during the first 12 hours and to help find the pattern of creatine kinase elevation, we took samples at 2 hour intervals after the study for the first 12 hours, and then at 24 hours in the first 8 patients. Because no elevation in creatine kinase B-subunit activity was observed in these patients, and elevated total creatine kinase activity appeared to consistently peak after the first 12 hours, in the remaining patients samples were obtained less often:

4, 8, and 24 hours after electrophysiologic study (see Results). In addition, reference limits were determined by measuring total creatine kinase (160 subjects) and creatine kinase B-subunit (201 subjects) enzyme activity in asymptomatic ambulatory volunteers.

Each blood sample was allowed to clot at room temperature, centrifuged at 2,000 *g* for 10 minutes and decanted. Creatine kinase determinations were performed within 24 hours on the refrigerated (4°C) samples, or else the sample was stored for a maximum of 120 hours in a freezer at −20°C until analysis could be performed. Total creatine kinase activity was assayed kinetically at 37°C by the method of Szasz et al.[5]

Creatine kinase B-subunit dependent activity was determined at 37°C as the creatine kinase activity remaining after immunoinhibition with a creatine kinase M-subunit inhibiting antibody (anti-M). Because residual adenylate kinase activity from erythrocytes and other tissues can falsely elevate creatine kinase B-subunit activity, residual adenylate kinase activity was measured in all samples and subtracted from the apparent creatine kinase B-subunit activity if B-subunit activity exceeded the upper reference limit.[6]

The value of total creatine kinase and creatine kinase B-subunit activity was considered elevated if the value exceeded the normal range. In addition, total creatine kinase activity was also designated as elevated if the value increased by more than 2 times the baseline value. A twofold or more increase is significantly greater than the normal day-to-day variation in total creatine kinase activity of 25%.[7] Statistical methods included chi-square analysis and Student's *t* test for unpaired data when appropriate.

Results

Electrophysiologic studies: The duration of the electrophysiologic studies averaged 3 hours (range 1 to 4.5). An average of 3.1 (range 1 to 5) electrode catheters were used for each patient. No complications were noted during the study. No patient undergoing intracardiac electrophysiologic evaluation had clinical or electrocardiographic evidence of myocardial infarction.

Arrhythmias induced (Table I): Sustained ventricular tachycardia was initiated in 13 patients and ventricular fibrillation in 1. Four patients had only nonsustained ventricular tachycardia (7 to 26 beats) reproducibly initiated. One patient had atrial fibrillation induced by programmed stimulation. In the remaining 5 patients, no arrhythmias were initiated.

Methods of arrhythmia termination: Nine of the 14 patients with sustained ventricular arrhythmias during electrophysiologic testing required cardioversion because of rapid (less than 60 seconds lapsed time) hemodynamic collapse associated with loss of consciousness (Table I). Cardioversion was performed immediately upon the patient's loss of consciousness. Repetitive shocks were required in 5 patients. Total cumulative delivered energy required for cardioversion was 50 to 740 W-s.

In the 5 remaining patients with induced sustained ventricular tachycardia, the tachycardia was terminated by rapid ventricular pacing. Pacing terminated tachycardia within 5 minutes of onset in 4 patients and after 1 hour in the fifth patient, during which time left ventricular activation mapping was performed. Cuff blood pressure recordings obtained in 3 of the 5 patients demonstrated a systolic blood pressure recording of 100 mm Hg or greater and were within 20 mm Hg of baseline systolic blood pressure. In the remaining 2 patients ventricular tachycardia was terminated before cuff blood pressure could be obtained. One patient complained of anginal chest pain during the tachycardia.

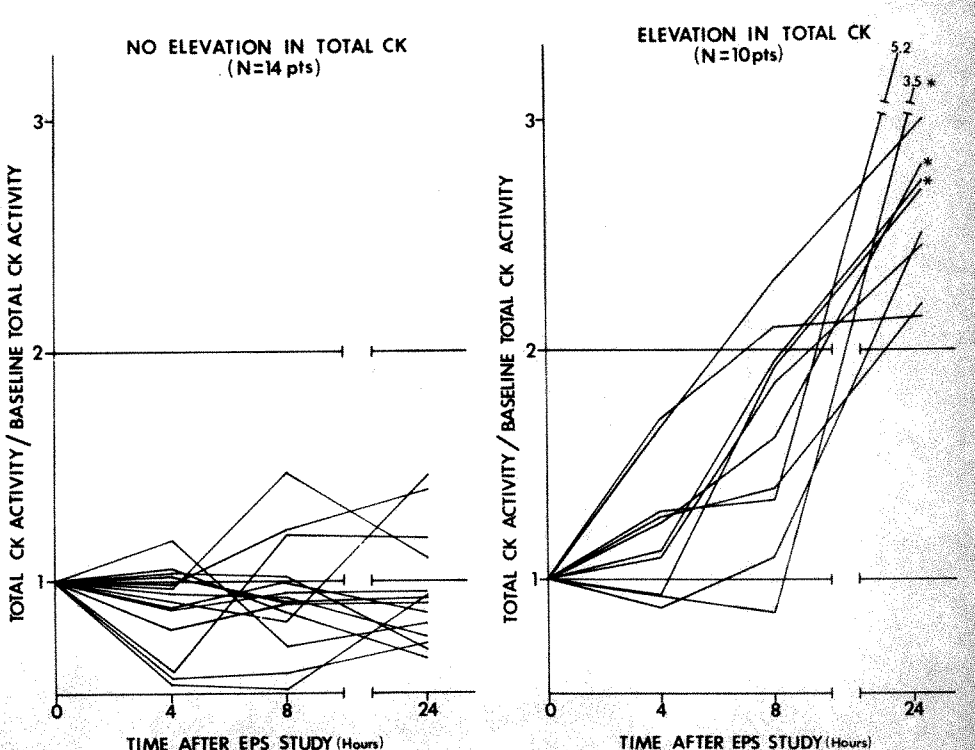

FIGURE 1. Pattern of total creatine kinase activity after electrophysiologic testing (EPS) for ventricular arrhythmias in the 14 patients without **(left panel)** and the 10 patients with **(right panel)** an elevation in total enzyme activity. Total creatine kinase (CK) activity after the study is compared with a baseline value (time = 0) of unity. Elevated total creatine kinase activity (greater than twice the baseline value) is noted at 24 hours in all 10 patients. **Asterisk,** peak total creatine kinase activity greater than upper reference limit.

The pain resolved within 30 seconds after termination of the arrhythmia by rapid pacing.

Effect on total and B-subunit creatine kinase activity: Reference limits for total creatine kinase activity were 22 to 222 units/liter in men and 34 and 140 units/liter in women. Changes in total creatine kinase activity after electrophysiologic study compared with a baseline value of unity are shown graphically in Figure 1. In 10 of 24 patients (42%), total creatine kinase activity after electrophysiologic study increased by more than twice the baseline value (Table I). All elevations in total creatine kinase activity were evident at 24 hours. However, in 2 patients, Cases 4 and 19, elevation was apparent as early as 8 hours.

The presence of coronary heart disease, arrhythmia induction, left ventricular catheterization, and the need for cardioversion did not significantly ($p > 0.05$) influence the likelihood of elevated total creatine kinase activity after electrophysiologic study. However, all 4 patients in whom delivered energy during cardioversion was 450 W-s or more had an elevation in total creatine kinase activity (Table I). Patients with elevations in total creatine kinase activity did not differ significantly from the group in which elevation was not observed with respect to the duration of electrophysiologic study (3.2 ± 0.7 versus 3.0 ± 1.0 hours) or the number of catheters used during the procedure (3.4 ± 0.7 versus 2.9 ± 1.2).

Creatine kinase B-subunit activity determined in the 201 control subjects established reference limits of 3 to 13 units/liter. B-subunit activity was below the upper reference limit at each time interval after electrophysiologic study in all 24 patients (Fig. 2). Furthermore, B-subunit activity did not increase by twice the baseline value in any patient. Thus, the elevation in total creatine kinase activity observed was due to creatine kinase MM isoenzyme rather than myocardial specific B-subunit activity.

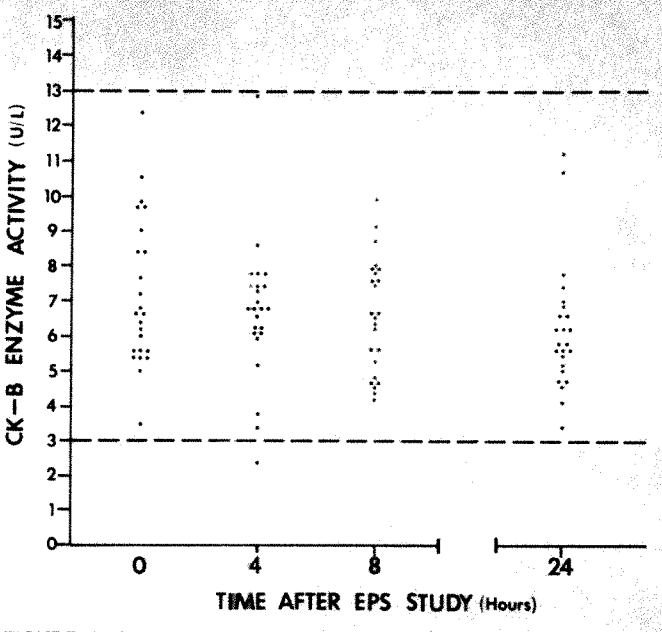

FIGURE 2. Creatine kinase B-subunit (CK-B) activity after electrophysiologic study for ventricular arrhythmia. **Dashed lines** mark the reference limits for B-subunit enzyme activity. All values for creatine kinase B-subunit activity fell below the upper reference limit at each time interval after the study. U/L = units/liter.

Discussion

Electrophysiologic studies are becoming more widely used for the diagnosis and therapy of malignant ventricular arrhythmias. The most common anatomic substrate associated with sustained ventricular tachycardia or fibrillation is severe multivessel coronary heart disease, usually with prior myocardial infarction, and often complicated by ventricular aneurysm formation.[8–10] Concern exists that induction of arrhythmia, particularly in patients with extensive coronary heart disease, might result in myocardial injury.[11] Accordingly, we sought to determine whether myocardial injury results from electrophysiologic studies for ventricular arrhythmias that involve (1) cardiac catheterization with electrode catheters, (2) programmed stimulation to attempt arrhythmia induction, and (3) the development of arrhythmias that frequently, similar to spontaneous arrhythmias, lead to hemodynamic collapse and require electrical countershock to restore normal sinus rhythm.

Elevation in total but not myocardial specific creatine kinase activity has been observed in 38 to 80% of patients after uncomplicated hemodynamic and angiographic cardiac catheterization.[12–15] Activity was reported to increase progressively and peak 12 to 24 hours after cardiac catheterization.[12–15] The increased total creatine kinase activity after cardiac catheterization is presumed to be related to either trauma to soft tissue or intramuscular injection of premedication. In addition, a modest increase in total creatine kinase activity has been reported in 6 to 50% of patients after elective electrical countershock of predominantly supraventricular arrhythmias.[16–18] More rarely, a slight elevation in MB creatine kinase coincident with total creatine kinase peak activity has been documented.[17] Other reports in animal models have suggested that there is potential for myocardial injury during closed-chest electrical countershock.[19]

In the present study total creatine kinase activity was elevated (greater than twice control values or greater than normal values, or both) in 42% of patients after electrophysiologic study. Arrhythmia induction or cardiac diagnosis did not influence total creatine kinase activity. All 4 patients who received at least 450 W-s of energy delivered during electrical cardioversion had an increase in total creatine kinase activity. Chest wall trauma related to the electrical countershock may have contributed to this increase. However, peak creatine kinase activity after electrical countershock has been observed to occur within 4 to 6 hours of the event.[17] Our findings of a more marked delay before maximal creatine kinase activity over a 24 hour period suggests that in our patients chest wall muscle trauma was not the only contributor to the increased total creatine kinase activity observed. The observation that total creatine

kinase activity became elevated 8 to 24 hours after electrophysiologic study is similar to the timing of the elevation after hemodynamic and angiographic cardiac catheterization.[12,13] Trauma to soft tissue related to catheter insertion may be the common denominator because none of our patients received intramuscular injections.

We found that creatine kinase B-subunit activity, which was determined after immunoinhibition of M-subunit activity, did not increase in any patient after electrophysiologic study. Because BB activity contributes negligibly to total B-subunit activity, creatine kinase B-subunit activity has been demonstrated almost uniformly to reflect myocardial specific MB activity.[20–22] Ljungdahl et al.[23] have demonstrated the effectiveness and sensitivity of measuring B-subunit activity in determining myocardial injury in patients with acute chest pain syndromes. Furthermore, Elser et al.[24] reported comparable sensitivity and specificity of B-subunit activity, measured 8 to 32 hours after suspected acute myocardial infarction, with MB activity measured using electrophoretic or chromatographic techniques. Thus, despite the fact that most of our patients had severe coronary heart disease, we could demonstrate no evidence of myocardial injury related to the stimulation procedure or arrhythmia induction as reflected by an increase in creatine kinase B-subunit activity.

It appears that electrophysiologic study including the induction of sustained ventricular tachyarrhythmia can safely be performed even in patients with underlying coronary heart disease. Nevertheless, the potential for myocardial damage during electrophysiologic study should not be ignored. Experienced and skilled technical assistance is crucial for reestablishing and maintaining electrocardiographic and hemodynamic stability.

Amiodarone for Control of Sustained Ventricular Tachyarrhythmia: Clinical and Electrophysiologic Effects in 51 Patients

HARVEY L. WAXMAN, MD, WILLIAM C. GROH, MD, FRANCIS E. MARCHLINSKI, MD, ALFRED E. BUXTON, MD, LAURA M. SADOWSKI, LEONARD N. HOROWITZ, MD, MARK E. JOSEPHSON, MD, and JOHN A. KASTOR, MD

We evaluated the electrophysiologic effects of amiodarone and its ability to control ventricular arrhythmia in a selected group of 51 patients with refractory sustained ventricular arrhythmia. Amiodarone in doses of 400 to 800 mg/day prolonged refractoriness in the atria, atrioventricular (AV) node, and ventricle as well as conduction through the AV node and His-Purkinje system. Although it had no effect on measurements of sinus nodal function (sinus nodal recovery time and sinoatrial conduction time), it prolonged the sinus cycle length and 2 patients required a permanent pacemaker for symptomatic sinus bradycardia. Amiodarone did not alter the ease of inducibility in any consistent manner, and only 5 of 43 patients (12%) who had inducible ventricular tachycardia before amiodarone therapy had none induced during amiodarone treatment. The clinical effectiveness of amiodarone could be evaluated in 46 patients followed up for 8.6 ± 6 months (range 0.5 to 22). It provided effective therapy in 23 patients (50%), partly effective therapy in 13 (28%), and was ineffective in 10 (22%). Adverse effects were noted in 28 of 51 patients (55%), and in 11 of these (22%) the drug had to be discontinued because of adverse effects.

We conclude that amiodarone is a useful agent for the treatment of refractory sustained ventricular arrhythmia. Its use should be reserved for patients with life-threatening sustained arrhythmia because of the significant incidence of adverse effects. Furthermore, good clinical response can be observed in patients receiving amiodarone in spite of continued inducibility.

Amiodarone hydrochloride is a benzofuran derivative which was first introduced as a coronary vasodilator and antianginal agent almost 20 years ago.[1,2] It was later discovered that amiodarone has antiarrhythmic properties and that its major effect is on action potential duration (class III antiarrhythmic agent).[3–5] Amiodarone is an attractive antiarrhythmic agent because it may be administered only once a day and is relatively nontoxic.[6–9] Studies in Europe, South America, and Canada[6–8,10,11] have suggested that amiodarone is effective for the treatment of both supraventricular and ventricular arrhythmia. The present study was undertaken to evaluate the electrophysiologic and clinical effects of oral amiodarone in a selected group of 51 patients with medically refractory sustained ventricular tachycardia (VT) or ventricular fibrillation (VF), or both.

Methods

Patients: The study group consisted of 51 patients (41 men and 10 women, aged 17 to 74 years) with medically refractory (see later) VT or VF. All patients except 1 (Case 11) had evidence of organic heart disease: coronary artery disease in 39, idiopathic cardiomyopathy in 5, mitral valve prolapse in 2, hypertensive cardiovascular disease in 1, hypertrophic cardiomyopathy in 1, left ventricular aneurysm in the absence of coronary artery disease in 1, and arrhythmogenic right ventricular dysplasia in 1.

All patients with a diagnosis of coronary heart disease had had at least 1 myocardial infarction. Infarction occurred at least 1 month before starting amiodarone therapy. Thirteen of the 39 patients with coronary heart disease had a left ventricular aneurysm when amiodarone was first administered. Nine of 39 patients had undergone prior left ventricular aneurysmectomy either for attempted control of VT (7 patients) or for hemodynamic indications (2 patients).

Left ventricular ejection fraction by nuclear blood pool scan or cardiac catheterization was measured in 44 of the 51 patients and was found to be 37 ± 17% (range 10 to 77); in 31 of the 39 patients with coronary artery disease, it was 30 ± 13% (range 10 to 67).

All patients had 1 to more than 100 episodes of sustained VT, cardiac arrest, or both, before amiodarone treatment was begun. Nineteen of the 51 patients (37%) had at least 1 cardiac arrest and 4 other patients experienced at least 1 syncopal episode. Thirty-nine patients (76%) required 1 to over 25 cardioversions for the termination of paroxysmal sustained VT or VF.

Previous antiarrhythmic therapy included 4.5 ± 1 (range 2 to 6) conventional agents per patient, 1 to 5 drug combinations per patient in 33 cases, and at least 1 other experimental antiarrhythmic agent in 14 cases. In some instances medications were discontinued because of the development of intolerable side effects. Failure of conventional or experimental antiarrhythmic agents was based on documented clinical recurrence of a sustained arrhythmia or continued inducibility during intracardiac electrophysiologic testing.

Monitoring facilities: During the initiation of therapy (2 to 3 weeks), all patients were continuously monitored in the Medical Intensive Care Unit or in an adjacent telemetry unit, both utilizing a computerized continuous recall arrhythmia monitoring facility (Becton-Dickinson, Electrodyne). Daily records were reviewed to help determine the effectiveness of treatment.

Electrophysiologic studies were conducted in all 51 patients. In 33 patients the studies could be conducted both before (control study) and after administration of amiodarone alone (treatment study). In 6 patients no antiarrhythmic drugs were given before the control study, but at the treatment study antiarrhythmic drugs in addition to amiodarone were administered because amiodarone alone had not controlled ventricular arrhythmia successfully. In 12 patients a control study during which the patients were taking no antiarrhythmic drugs could not be performed because of the presence of frequent episodic or incessant VT.

Electrophysiologic testing was performed in the nonsedated postabsorptive state after written informed consent was obtained.[12] Three or 4 electrode catheters were inserted percutaneously into the femoral or antecubital veins and positioned under fluoroscopic guidance into the high right atrium, the atrioventricular junction to obtain a recording of the His bundle, the coronary sinus, and the right ventricular apex. Programmed stimulation was performed using pulses of 1 ms duration at twice diastolic threshold using a custom-designed programmable stimulator and an optically isolated constant current source (Bloom Associates, Narberth, Pennsylvania).

The following electrophysiologic measurements were made: Corrected sinus nodal recovery time, sinoatrial conduction time, A-H and H-V intervals during normal sinus rhythm, A-H interval at multiple atrial paced cycle lengths, atrial paced cycle length to AV node Wenckebach conduction, atrial effective refractory period, and ventricular effective refractory period.[13] At least 3 atrial cycle lengths were used to evaluate the corrected sinus nodal recovery time, most often 600, 500, and 400 ms. The length of pacing at each cycle length and the interval between each pacing period was at least 1 minute. The sinus nodal recovery time was corrected by subtracting the sinus cycle length. The sinoatrial conduction time was measured by the Narula method and was divided by 2.[14] Refractory periods were measured at the same paced cycle length and site of stimulation before and after therapy for purposes of comparison.

The stimulation protocol for VT during control and all subsequent studies consisted of the introduction of single, double, and triple ventricular extrastimuli during sinus rhythm or ventricular paced rhythm at multiple cycle lengths (800 to 400 ms), or both, and during bursts of rapid pacing (400 to 250 ms for 15 to 30 seconds) at the right ventricular apex. If VT was not induced using this protocol, similar stimulation was performed at the right ventricular outflow tract. No patient in this series required left ventricular stimulation or isoproterenol for induction. Two catheters were routinely employed during follow-up testing.

Amiodarone administration: Amiodarone therapy was begun with a loading dose of 1,400 mg/day as a single dose with meals for an initial loading period of 11.1 ± 6.6 days (range 7 to 35). During the early portion of the loading period, conventional antiarrhythmic agents were often given, especially in cases of incessant or frequent or very rapid VT.

In the first 25 patients studied, the duration of loading and subsequent maintenance dose of amiodarone was based upon the level of spontaneous ventricular ectopic activity. The patients were continued on a loading dose of amiodarone until continuous monitoring revealed fewer than 6 premature ventricular depolarizations per hour and no triplets or VT for 72 hours. The maintenance dose of amiodarone was derived from the number of days of loading required in Patients 1 through 25 as follows: 7 days or fewer, 400 mg/day; 7 to 14 days, 600 mg/day; and more than 14 days, 800 mg/day. In Patients 26 through 51 the criteria were modified so that the maintenance dose was begun when no VT was detected for 72 hours. Again, the amount of the maintenance dose was based on the number of days of loading.

Electrophysiologic testing on amiodarone was performed after the patients had been on their maintenance dose for 2 to 108 days. Forty-nine of 64 electrophysiologic studies were performed after the patients had been on the maintenance dose for 4 to 8 days. Initially, the patients in whom VT could still be induced were reloaded with 1,400 mg/day and then given a dose 200 mg greater than that they had received previously. Seventeen patients underwent 18 reloading periods (1,400 mg/day) of 4.1 ± 1.4 days (range 2 to 8) followed by 10 ± 11 days of maintenance therapy before repeated electrophysiologic study because of continued inducibility. However, tachycardia was inducible in all patients on amiodarone despite reloading (see Results), and this method was abandoned. Patients were then continued on amiodarone without reloading despite inducibility. Reloading (3 to 8 days of 1,400 mg/day) was performed in 4 other patients because of spontaneous VT occurring after 1 to 20 days on a maintenance dose.

In 9 cases a type I antiarrhythmic agent was added and electrophysiologic testing repeated if amiodarone alone had failed to prevent spontaneous or induced VT. Fifteen patients were treated with a type I antiarrhythmic agent (quinidine, 13; procainamide, 2) in addition to amiodarone either because it slowed the rate of induced VT and we concluded the patients would be more likely to survive a recurrence (5 cases) or for clinical control (10 cases).

Routine laboratory tests before amiodarone and during follow-up included chest x-ray, complete blood count and differential, liver function tests, electrolyte determination, urinalysis, thyroid function tests, electrocardiogram, and ophthalmologic examination. Holter monitoring and nuclear gated blood pool scans were performed before the start of amiodarone therapy when possible. Follow-up evaluation was performed every 1 to 3 months at the University of Pennsylvania, or when the patients lived at a long distance, by the patient's private physician with telephone or mail follow-up

to one of the investigators. Routine laboratory tests, electrocardiogram, 24 hour Holter monitoring, and physical examinations were performed during follow-up visits. Ophthalmologic examinations were performed at similar intervals whenever possible.

All patients received artificial tear solution 4 times a day because it has been suggested that this might lessen the development of corneal microdeposits.[15]

The efficacy of amiodarone was assessed during follow-up with the following criteria: It was judged (a) *effective* if no sustained or symptomatic arrhythmia occurred after a maintenance dose was established, (b) *partly effective* if the frequency of episodes decreased or if another medication that was ineffective alone was effective in combination with amiodarone, and (c) *ineffective* if arrhythmia occurrence was not favorably altered or sudden death occurred.

Statistical analysis of electrophysiologic data was performed using a paired Student's *t* test. Data are expressed as mean ± standard deviation unless otherwise specified.

Results

Electrophysiologic Data (Table I)

Comparison of electrophysiologic effects of amiodarone was made between control values and the highest maintenance dose tested in each patient. Twenty-five patients were taking digoxin, 3 propranolol, and 8 digoxin and propranolol during the control electrophysiologic study. In patients taking digoxin or propranolol, or both, electrophysiologic data were compared only when the dose of these medications were unchanged between the control and the treatment study.

Amiodarone had no statistically significant effect on measurements of sinus nodal function (corrected sinus nodal recovery time and sinoatrial conduction time). However, the sinus cycle length increased by 84 + 202 ms in the 24 patients in whom it could be assessed in the absence of additional agents. Two patients required a permanent pacemaker because of severe symptomatic sinus bradycardia. Amiodarone prolonged the atrial effective refractory period by 42 ± 43 ms in 21 patients ($p < 0.001$), prolonged the A-H interval during sinus rhythm by 14 ± 21 ms in 28 patients ($p < 0.001$), prolonged the A-H interval measured at the same paced cycle length by 40 ± 57 ms in 16 patients ($p < 0.01$), prolonged the paced cycle length to AV node Wenckebach conduction by 113 ± 100 ms in 27 patients ($p < 0.001$), prolonged the H-V interval by 4 ± 9 ms in 35 patients ($p < 0.01$), and prolonged the ventricular effective refractory period by 24 ± 33 ms in 27 patients ($p < 0.001$).

The effects of amiodarone on the H-V interval, although statistically significant, were small. The H-V interval during sinus rhythm was prolonged after amiodarone by 10 to 20 ms in 11 patients. The H-V interval changed by 5 ms or less in 19 patients. In 1 patient infra-His bundle block was observed during atrial pacing at a paced cycle length of 600 ms for which a permanent pacemaker was implanted. This patient had a prolonged H-V interval of 60 ms before starting amiodarone.

Effect of amiodarone on induction and cycle length of VT: VT was induced in the control study in 43 of the 51 patients, 33 of whom were taking no antiarrhythmic drugs. Eight of 51 patients spontaneously developed VT either very frequently or incessantly, and consequently induction was not evaluated. At the treatment study in 5 of 43 patients, VT could no longer be induced. The administration of another antiarrhythmic drug in addition to amiodarone had no effect on inducibility in 9 patients tested. Ease of inducibility was not altered by amiodarone in any consistent fashion (Fig. 1).

The cycle length of 34 episodes of sustained VT induced in 34 patients during the control study (on no antiarrhythmic medication other than digoxin, propranolol, or both) was 303 ± 67 ms, and during the treatment study (on amiodarone alone) was 343 ± 77 ms ($p = 0.01$). Morphologically identical VT was induced during the control study and during the treatment study in 20 patients. The VT cycle length increased from 293 ± 64 to 357 ± 84 ms in these patients ($p < 0.001$) (Fig. 2). In 14 patients the morphology of the VT induced during the control and treatment studies was not identical. However, the morphology of VT induced was similar to that observed either spontaneously or during induction study on other antiarrhythmic drugs in al-

TABLE I Electrophysiologic Data

	Baseline (ms)	Amiodarone (ms)	Difference (ms)	p Value	Patients (n)	Treatment Period (Days)
Sinus cycle length	844 ± 157	928 ± 238	84 ± 202	<0.05	24	30 ± 28
Corrected sinus nodal recovery time	271 ± 118	279 ± 124	8.0 ± 148	NS	25	23 ± 16
Sinoatrial conduction time	90 ± 51	96 ± 47	7.0 ± 45	NS	16	20 ± 14
Atrial effective refractory period	252 ± 40	294 ± 39	42 ± 43	<0.001	21	24 ± 22
A-H (resting)	90 ± 24	105 ± 22	14 ± 21	<0.001	28	25 ± 25
A-H interval (at same paced cycle length)	115 ± 33	155 ± 54	40 ± 57	<0.01	16	18 ± 11
Paced cycle length to AV node Wenckebach	360 ± 61	472 ± 99	113 ± 100	<0.001	27	22 ± 15
H-V interval	62 ± 12	66 ± 13	4 ± 9	<0.01	35	28 ± 25
Ventricular effective refractory period	260 ± 23	284 ± 34	24 ± 33	<0.001	27	31 ± 27

most all cases. The addition of type I antiarrhythmic agent in 9 cases (quinidine in 4, procainamide in 4, and disopramide in 1) resulted in a further significant increase in tachycardia cycle length from 288 ± 67 to 354 ± 95 ms ($p < 0.001$).

Clinical Efficacy of Amiodarone for Control of Ventricular Tachyarrhythmia (Table II)

The clinical value of amiodarone could be evaluated in 46 of the 51 patients. Five patients were not included in long-term evaluation for the following reasons: 2 had left ventricular aneurysmectomy and endocardial resection, 1 was discharged on another agent because of continued inducibility (at a time early in the study when we thought that noninducibility was required for successful treatment), and 2 patients died from congestive heart failure without VT recurrence after 2 and 3 weeks of amiodarone treatment. These 46 patients were followed up for a mean of 8.6 ± 6 months (range 0.5 to 22). All patients except 1 (Case 21, see later) in whom amiodarone was considered effective or partly effective were treated for at least 3 months.

Effective group: Amiodarone provided effective therapy in 23 of 46 patients (50%). In 7 of these patients, amiodarone had to be discontinued because of side effects which developed after 6 to 19 months of treatment. Four other patients died during follow-up. Two patients died from congestive heart failure after 6 and 7 months of therapy, respectively, and 1 died from gram-negative sepsis after 3 months of therapy. One patient died from rapid VT 11 days after amiodarone was discontinued for no apparent reason by the patient's private physician.

Partly effective group: Amiodarone was considered partly effective in 13 of 46 patients (28%). In 3 of these 13 patients, a type I agent was added because of the induction of VT associated with cardiac arrest during electrophysiologic study. The type I agent was administered because it decreased the rate of induced VT to a more tolerable rate, and we concluded that the patients would be more likely to survive a recurrence. A type I antiarrhythmic agent, which was ineffective before amiodarone, was needed in 9 patients for control of spontaneous sustained VT. In 1 patient (Case 26) occasional episodes of VT on amiodarone alone were well tolerated. In this patient the intermittent episodes of VT were terminated at home with an oral dose of procainamide.

Three patients in whom amiodarone was considered partly effective had to have the medication discontinued because of adverse effects which developed after 8, 9, and 18 months of treatment. One patient died from congestive heart failure and 1 from pneumonitis after 1.5 and 5 months of therapy, respectively. In the patient who died from congestive heart failure (Case 21) the combination of amiodarone and quinidine successfully suppressed incessant VT. This was the only patient treated with amiodarone for less than 3 months in whom it was considered either effective or partly effective.

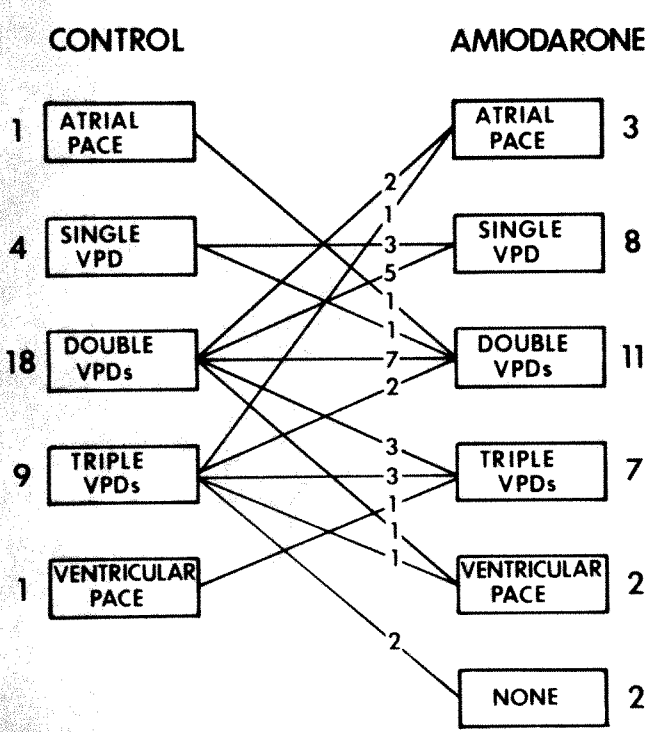

FIGURE 1. Mode of induction of ventricular tachycardia in 33 patients during the control study and during the treatment study with amiodarone. Amiodarone failed to alter the ease of inducibility in any consistent fashion.

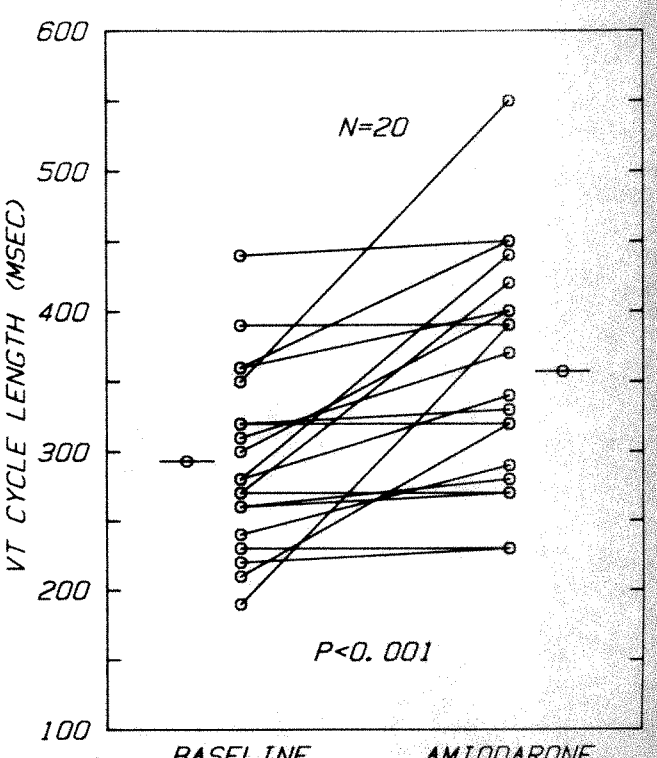

FIGURE 2. Effect of amiodarone on induced VT cycle length in the 20 episodes of VT with similar morphology during the baseline (control) and amiodarone (treatment) study.

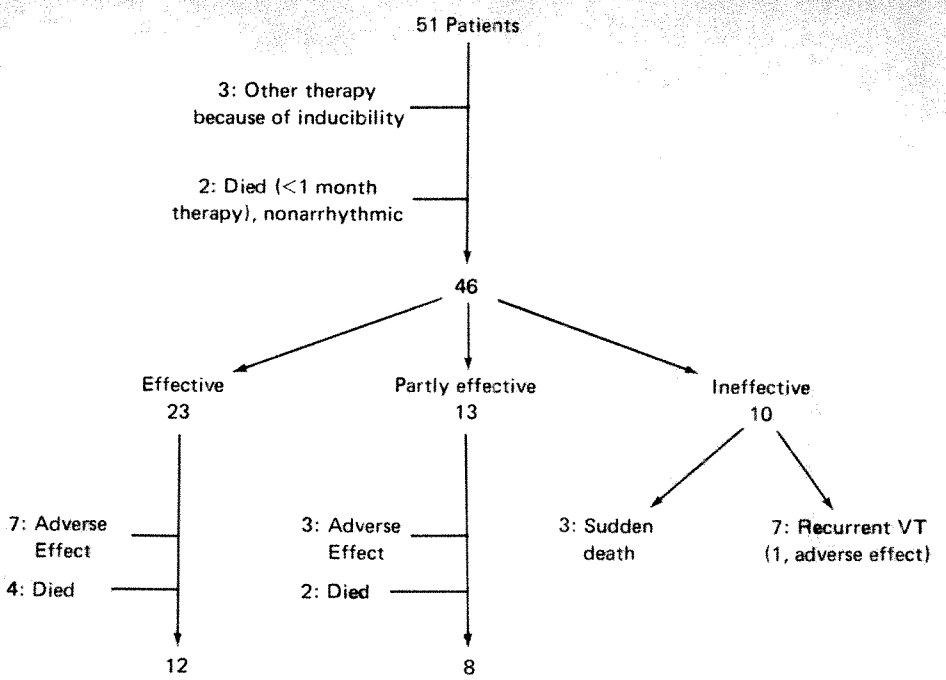
TABLE II Clinical Efficacy of Amiodarone



Ineffective group: Amiodarone was ineffective in controlling arrhythmia in 10 of 46 patients (20%). Three of the 10 patients in whom amiodarone was judged ineffective died suddenly. One of these patients (Case 25) was placed on amiodarone therapy because of hemodynamically well-tolerated incessant VT which was controlled with amiodarone and quinidine. This patient had never had cardiac arrest before amiodarone and had tolerated incessant VT for more than 1 week before amiodarone therapy. Furthermore, quinidine therapy was ineffective but well tolerated before amiodarone. He died suddenly 4 months after starting amiodarone in spite of good control of clinical VT. The other 2 patients who died suddenly after 1.5 and 11.5 months of therapy were being treated for paroxysmal sustained VT, but only 1 patient had had a prior cardiac arrest. The latter patient was placed on quinidine in addition to amiodarone because it slowed the rate of induced VT. Quinidine had been well tolerated but ineffective before amiodarone. This patient had no recurrence for the 11.5 months before sudden death. A fourth patient (Case 22) died from infarcted bowel after 5 months of therapy but continued to have recurrent episodes of VT in spite of amiodarone.

Four of the remaining 6 patients in whom amiodarone was judged ineffective had recurrences of VT similar to those observed before amiodarone. One patient had a recurrence after 2 weeks, 2 patients after 1 month, and 1 patient on quinidine and amiodarone after 5 months. This patient was placed on quinidine in addition to amiodarone because it slowed the rate of induced VT. Amiodarone was discontinued because of an adverse effect (pustular psoriasis) in the patient (Case 24) who had a recurrence after 2 weeks.

One of the remaining 2 patients (Case 13) in whom amiodarone was considered ineffective developed rapid VT that degenerated to VF 2 weeks after starting amiodarone. Before amiodarone the patient had had well-tolerated episodes of uniform VT. For this reason the medication was discontinued. Ninety days after starting amiodarone, the other patient (Case 9) had a recurrent syncopal episode which was presumed secondary to ventricular arrhythmia. Amiodarone was considered ineffective and was discontinued.

Results of 24 Hour Holter Monitoring (Table III)

Twenty-four hour Holter monitor recordings were available in 38 patients while on an oral dose of amiodarone or amiodarone plus a type I agent. Amiodarone had been judged (see earlier) effective in 21 of these patients, partly effective in 13, and ineffective in 4. One additional patient had abolition of incessant VT on amiodarone plus quinidine, although a 24 hour Holter monitor recording was not available for analysis. Furthermore, adjustment of amiodarone dosage in the first 25 patients was based upon daily analysis of computerized electrocardiographic telemetry monitoring as detailed in the Methods section.

Twenty patients who had a satisfactory (effective or partly effective) clinical response to amiodarone had 0 to 10 ventricular premature depolarizations (VPDs) on 24 hour Holter monitoring. Thirteen patients with a satisfactory clinical response to amiodarone had 10 to over 1,000 VPDs/24 hours; the remaining patient had episodes of nonsustained VT. Holter recordings were only available in 4 patients who were clinical failures; none had total abolition of ventricular ectopic activity, and 2 had episodes of nonsustained VT.

TABLE III Results of 24 Hour Holter Monitoring (n = 38)*

	VPD/24 Hours				
	0–10	10–100	100–1,000	>1,000	NVST
Effective	11	4	4	2	. . .
Partly effective	9 (8)	1 (1)	1	1	1
Ineffective	. . .	1 (1)	1	. . .	2 (1)

* Numbers in parentheses indicating number of patients receiving type I antiarrhythmic agent in addition to amiodarone. NSVT = nonsustained ventricular tachycardia, 6 beats to 1 minute; VPD = ventricular premature depolarization.

Twenty-four hour Holter monitor recordings during the control state and after amiodarone were available in 14 patients. In the remaining patients, no Holter monitor recording was available off antiarrhythmic medication. Of 3 patients with incessant VT, 1 had less than 10 and 1 had 10 to 100 VPDs per 24 hours, and 1 continued to have episodes of nonsustained VT while on amiodarone. In the 11 remaining patients, the number of VPDs per 24 hours was unchanged or decreased in all instances.

Adverse Effects (Table IV)

All except 2 patients who had a side effect requiring withdrawal of amiodarone were taking 800 mg/day. Major side effects requiring discontinuance of the drug occurred in 11 patients, and minor side effects requiring no change or a decrease in dose occurred in 17 patients (excluding patients with photosensitivity and corneal microdeposits).

Neurologic: Neurologic complications occurred in 5 patients and included peripheral neuropathy in 3 and extrapyramidal symptoms in 2. Four of the 5 patients who exhibited neurologic complications were taking 800 mg/day of amiodarone for 4 to 18 months. In all patients neurologic symptoms improved 1 to 4 months after withdrawal of amiodarone. Of the 2 patients who had extrapyramidal symptoms, 1 had improvement in symptoms after a decrease in dosage from 600 to 400 mg/day. The other patient previously on 800 mg/day of amiodarone was started on 400 mg daily after a 3 week hiatus in therapy. He has done well for 3 months on the lower dose of amiodarone.

Hepatic: Liver toxicity was observed in 10 patients. Its manifestations included clinical evidence of hepatitis in 2 patients and asymptomatic elevations in liver function tests in 8 patients. Most elevations in liver function tests were mild and in the range of 1.5 to 3 times the normal values for alkaline phosphatase and serum glutamic oxalacetic and pyruvic transaminase. Amiodarone was discontinued in the 2 patients with symptoms. In 1 patient all tests returned to normal after several months, while the other patient has remained jaundiced with ascites and elevated liver function tests 6 months after amiodarone withdrawal.

Liver biopsy was performed in 1 of the symptomatic and in 3 of the asymptomatic patients with liver function abnormalities. Attempted liver biopsy was unsuccessful in 1 symptomatic patient because of ascites. In the 1 symptomatic patient and 2 of the asymptomatic patients, biopsy revealed prominent micro- and macrovesicular cytoplasmic fatty infiltration with minimal inflammatory reaction. In the fourth patient with suspected amiodarone liver toxicity, biopsy revealed evidence of probable recent viral hepatitis. All elevations of liver function tests in asymptomatic patients resolved spontaneously or after the amiodarone dosage was decreased.

Dermatologic: Many of the patients exhibited mild to moderate photosensitivity that was controlled with a decrease in sun exposure and the use of sunscreens. One patient had a disabling photosensitivity that was not adequately controlled with sunscreen or a decrease in dosage from 800 to 400 mg daily. In 1 other patient with preexisting active psoriasis, amiodarone was stopped because of pustular psoriasis which developed 2 weeks after amiodarone was started.

Cardiac: Five patients died from congestive heart failure after taking amiodarone for 2 weeks to 7 months. The ejection fraction in these patients ranged from 13

TABLE IV Adverse Effects*

	Instances	Time to Development (mo)
Neurologic		
Peripheral neuropathy	3 (3)	5, 15, 18
Extrapyramidal symptoms	2	3, 4
Liver toxicity		
Symptomatic	2 (2)	6, 10
Asymptomatic (less than 3 times normal, except in 1 patient—5 times normal)	8†	As early as 0.5
Cutaneous		
Photosensitivity, severe	1 (1)	6
Pustular psoriasis	1 (1)	0.5
Increased pigmentation	2	8, 12
Cardiac		
Increased CHF	7	As early as 1
Bradycardia requiring permanent pacemaker	5	As early as 3
Ocular		
Corneal microdeposits	15 of 21‡	As early as 0.5
Photosensitivity	2	6, 12
Thyroid		
Hyperthyroidism	1	8
Pulmonary	5 (4)	5, 8, 9, 10, 10

* Numbers in parentheses indicate the number of patients in whom drug was discontinued because of adverse effect. CHF = congestive heart failure.
† One was probably due to viral hepatitis.
‡ Fifteen of 21 patients with eye examinations on amiodarone for more than 1 month.

to 51 percent before starting amiodarone. In 4 of the 5 patients the ejection fraction was under 30 percent. Two other patients with an ejection fraction of 39 and 45 percent had increased congestive heart failure after amiodarone therapy for 10 and 13 months, respectively. Congestive heart failure improved with conventional therapy and a decrease in amiodarone dosage in these 2 patients.

Five patients required a permanent pacemaker after amiodarone for the following reasons: symptomatic sinus bradycardia in 2, symptomatic slow ventricular rate during atrial fibrillation in 1, heart block in 1, and overdrive suppression of intermittent slow VT with AV sequential pacing in 1.

Ophthalmologic: Asymptomatic corneal microdeposits were observed in 15 of 21 patients who had at least 1 ophthalmologic slit lamp examination while on amiodarone for more than 1 month. Deposits were observed as early as 3 weeks after starting amiodarone. In 2 patients ocular photosensitivity was easily controlled with tinted eyeglasses, and 1 patient developed chromatic aberration in association with very heavy corneal microdeposits.

Thyroid: Clinical hyperthyroidism was observed in 1 patient and required treatment with antithyroid medication.

Pulmonary: Five patients exhibited pulmonary complications. They presented with fever, dyspnea, hypoxia, and infiltrates on chest x-ray after 5 to 10 months of amiodarone therapy. Three patients were taking 800 mg/day and 2 were taking 600 mg/day. Lung biopsy in 4 patients revealed interstitial fibrosis and alveolar exudate, similar to the pathologic findings previously reported.[16] Three patients improved with discontinuation of amiodarone and institution of glucocorticoid therapy. One patient died at another hospital in acute respiratory failure 16 hours after admission with a 2 week history of an upper respiratory tract infection. The remaining patient died from acute respiratory and hemodynamic collapse 1 week after stopping amiodarone therapy.

Discussion

Previous studies: Previous studies performed outside the United States[6,8,11] and recent trials in America[16–19] suggest that amiodarone may be an effective therapeutic agent for control of ventricular arrhythmia. The largest series reported to date[6] using amiodarone for control of ventricular arrhythmia found an 82% response rate. However, in this series of 145 patients with ventricular arrhythmia, only 8 patients had VT or VF associated with ischemic heart disease and left ventricular aneurysm. Six of these 8 patients had what is described as an excellent result during follow-up up to 26 months. A more recent report from the same group of investigators[8] reported an 87% response rate in 23 patients with sustained, recurrent, symptomatic VT followed up for a mean of 24.2 months. Similarly, Heger et al.[16] recently reported a 67% success rate in 40 patients with sustained recurrent VT or VF and 5 patients with nonsustained VT resistant to therapy with other antiarrhythmic agents followed up for a mean of 12.7 months. Thirty patients in this group had ischemic heart disease, but the number of patients with prior documented myocardial infarction and left ventricular aneurysm is not stated.

Electrophysiologic effects: Amiodarone prolongs refractoriness and depresses conduction throughout the heart. Wellens et al.[10] reported that amiodarone prolonged effective refractory periods in the atria, AV node, accessory pathway, and ventricles as well as conduction through the AV node in patients with the Wolff-Parkinson-White syndrome. Heger et al.[16] reported similar electrophysiologic effects on AV nodal conduction and the ventricular effective refractory period in a small group of patients with ventricular arrhythmia, although they noted no prolongation of atrial effective refractory period. They observed a significant increase in sinus cycle length and no significant effects on the H-V interval.

We observed prolonged refractoriness in the atria and ventricles and prolonged conduction through the AV node in our patients. The drug did not affect measures of sinus nodal function, although the sinus cycle length was significantly increased and some patients did develop significant sinus bradycardia. We also observed a small but significant prolongation of the H-V interval, although it was prolonged by 20 ms or more in only 2 patients. One of these 2 patients developed infra-His bundle block during atrial pacing requiring a permanent pacemaker. Some of our patients were on digoxin, propranolol, or both, at the time of control and treatment studies. Although the dosages of these medications were similar at both studies, we cannot exclude the possibility of drug interactions with amiodarone that might have affected the observed results.

Antiarrhythmic effects: In the present study, all patients except 2 had either spontaneous sustained VT or VF. These 2 patients had a history of recurrent syncope with inducible sustained VT during electrophysiologic study. All patients failed multiple trials of antiarrhythmic agents, and combination of agents. Other experimental agents were tried in 14 patients. Forty % of the patients had at least 1 cardiac arrest before starting amiodarone, and 77% required at least 1 cardioversion. Twenty-two of the 39 patients with coronary heart disease had left ventricular aneurysm or had already undergone left ventricular aneurysmectomy. Most patients had evidence of significant left ventricular dysfunction, and the mean ejection fraction in those patients with coronary heart disease was 30 ± 12%. Thus, amiodarone was used more or less as the last resort in this group of patients.

Several investigators have shown that a drug which prevents induction of VT in the electrophysiologic laboratory is associated with short- and long-term arrhythmia suppression.[20–23] Conversely, induction of sustained ventricular tachyarrhythmia during standard drug therapy in the electrophysiologic laboratory usually predicts recurrence on the particular regimen

tested. In contradistinction, a dissociation between arrhythmia induction and clinical response with amiodarone was recently reported.[16] Similarly, we observed that although amiodarone suppressed the induction of ventricular arrhythmia in only 5 of 43 patients, total clinical suppression of arrhythmia was observed in 23 of 46 patients.

The reason for the dissociation between tachycardia induction and clinical response to amiodarone is unknown, although in some patients it may be related to suppression of spontaneous ventricular ectopic activity. In this way amiodarone may be effective in some patients by abolishing the triggers that initiate reentrant ventricular arrhythmias rather than effecting the tachycardia circuit. However, amiodarone must also have some effects on the ventricular arrhythmia circuit as evidenced by its ability to prolong tachycardia cycle length. Furthermore, 14 patients had a good clinical response to amiodarone in spite of continued ventricular ectopic activity on 24 hour Holter monitoring. The reason for achieving arrhythmia control in those patients without abolition of ventricular ectopic activity or noninducibility in the electrophysiologic laboratory is not clear. We cannot exclude the possibility that amiodarone may be effective in some patients by selectively suppressing premature beats that occur at critical coupling intervals responsible for triggering sustained tachyarrhythmia, since we did not measure ventricular premature beat coupling intervals.

Toxic side effects: Amiodarone reportedly has a low incidence of adverse effects.[6,7,18,19] As in earlier reports,[24,25] many of our patients treated with amiodarone developed corneal microdeposits as early as 3 weeks after starting therapy. These deposits were only troublesome in 1 patient. On the other hand, neurologic, hepatic, cutaneous, and thyroid complications were troublesome and necessitated withdrawal of the medication in several instances. In fact, 8 of 21 patients (38%) on 800 mg/day for more than 3 months had side effects severe enough to require discontinuation of the medication. Overall, 10 of 36 patients (28%) with a good clinical response had to have the drug discontinued because of adverse effects.

Neurologic,[26–28] cutaneous,[25,29,30] thyroid,[31,32] and pulmonary[16,33] adverse effects similar to those observed in our patients have been previously noted during amiodarone administration. However, to our knowledge, no prior instances of significant hepatic toxicity have been described except for transient elevations of hepatic enzymes.[16,18] In fact, Plomteux et al.[34] specifically reported good hepatic tolerance to amiodarone in 30 patients treated with 300 to 600 mg/day for 32 weeks. Although in our series most patients with liver function abnormalities were asymptomatic, 2 developed clinical hepatitis necessitating withdrawal of amiodarone treatment. Liver biopsy in 1 symptomatic and 2 asymptomatic patients revealed evidence of fatty infiltration. One patient still had active liver disease 6 months after withdrawal of amiodarone. However, since liver biopsy was not accomplished in this patient, a definite diagnosis of amiodarone toxicity cannot be established. Fortunately, in all instances except this one the adverse effects abated after discontinuation of amiodarone or a decrease in dosage.

One of our patients (Case 13) developed rapid VT associated with cardiac arrest requiring defibrillation 2 weeks after starting amiodarone. The arrhythmia began as a wide complex rapid pleomorphic VT characteristic of torsade de pointes and eventually degenerated to VF. Before amiodarone this patient had recurrent episodes of morphologically uniform and well-tolerated VT. The corrected Q-T interval was mildly prolonged to 0.47 second, and there was no other apparent metabolic derangement to account for the arrhythmia. The amiodarone was withdrawn, and no further recurrence of rapid VT or torsade de pointes was noted. One case of torsade de pointes tachycardia developing with amiodarone was previously reported in the European literature.[35]

Previous studies in animals[36] *and human beings*[37] *have indicated that amiodarone is a potent peripheral vasodilator and may, therefore, have beneficial effects on left ventricular function.* However, amiodarone is also a potent competitive nonselective catecholamine antagonist which might contribute to a worsening of congestive heart failure.[36] Several of our patients had an increase in congestive heart failure while on amiodarone. Since most of the patients in this series had evidence of significant left ventricular dysfunction before amiodarone therapy, it is unclear whether this exacerbation of failure was due to amiodarone or the natural history of the underlying disease. Furthermore, when amiodarone interruption was associated with an improvement in congestive heart failure, it was accompanied by changes in concomitant therapy. Further studies are needed to define the effects of prolonged amiodarone treatment on left ventricular function in patients with significant underlying heart disease.

The development of pulmonary complications on amiodarone has been reported previously and is probably the most troublesome adverse effect.[16,33] Our 5 cases add further evidence that this complication is indeed related to amiodarone therapy. The relationship of amiodarone dosage to the development of pulmonary toxicity is unclear. In 1 patient on amiodarone, 400 mg/day, for 1 month pulmonary toxicity was reported.[33] The patients in our series who developed pulmonary toxicity were taking 600 to 800 mg/day for 5 to 10 months.

The high incidence of adverse effects observed in our population may be related to the high dose employed in some cases. Nevertheless, others have reported an extremely low incidence of side effects using comparable doses.[8,18] The reasons for this discrepancy are unclear.

Conclusions: Amiodarone provided effective or partly effective treatment in 36 of 46 (78%) of our patients with medically and, in some cases, medically and surgically refractory ventricular tachyarrhythmia. It appears that electrophysiologic testing cannot help

guide therapy since in most patients tachycardia remains inducible on amiodarone in spite of good clinical results. However, electrophysiologic testing may be indicated in those patients with rapid, poorly tolerated VT before amiodarone therapy. In these patients electrophysiologic testing on amiodarone might help to determine whether the addition of another antiarrhythmic agent is indicated. The addition of another antiarrhythmic agent might slow the rate of induced VT so that if recurrences occur, they may not be associated with cardiac arrest.

Amiodarone in the doses tested, especially 800 mg/day, was associated with a significant incidence of adverse effects which frequently require a decrease in dosage or even discontinuation of treatment. Based on these results, we believe the long-term treatment with more than 600 mg/day of amiodarone should be avoided.

Further clinical testing of amiodarone is warranted since it provided effective therapy in patients with refractory ventricular tachyarrhythmia. At present, its use should be reserved for patients with medically refractory sustained ventricular tachyarrhythmia. In this group of patients, the potential for adverse effects is acceptable based on a favorable risk-benefit ratio.

Acknowledgment

We express our gratitude to Marilyn Ezri, MD, Michael Cain, MD, Martin Gardner, MD, and to the electrophysiology technicians for their assistance in performing the electrophysiologic studies. We also thank Kathleen Cioschi and Pat Wyatt for their excellent preparation of the manuscript. The amiodarone (Cordarone) was generously supplied by LaBaz Laboratories, Paris, France.

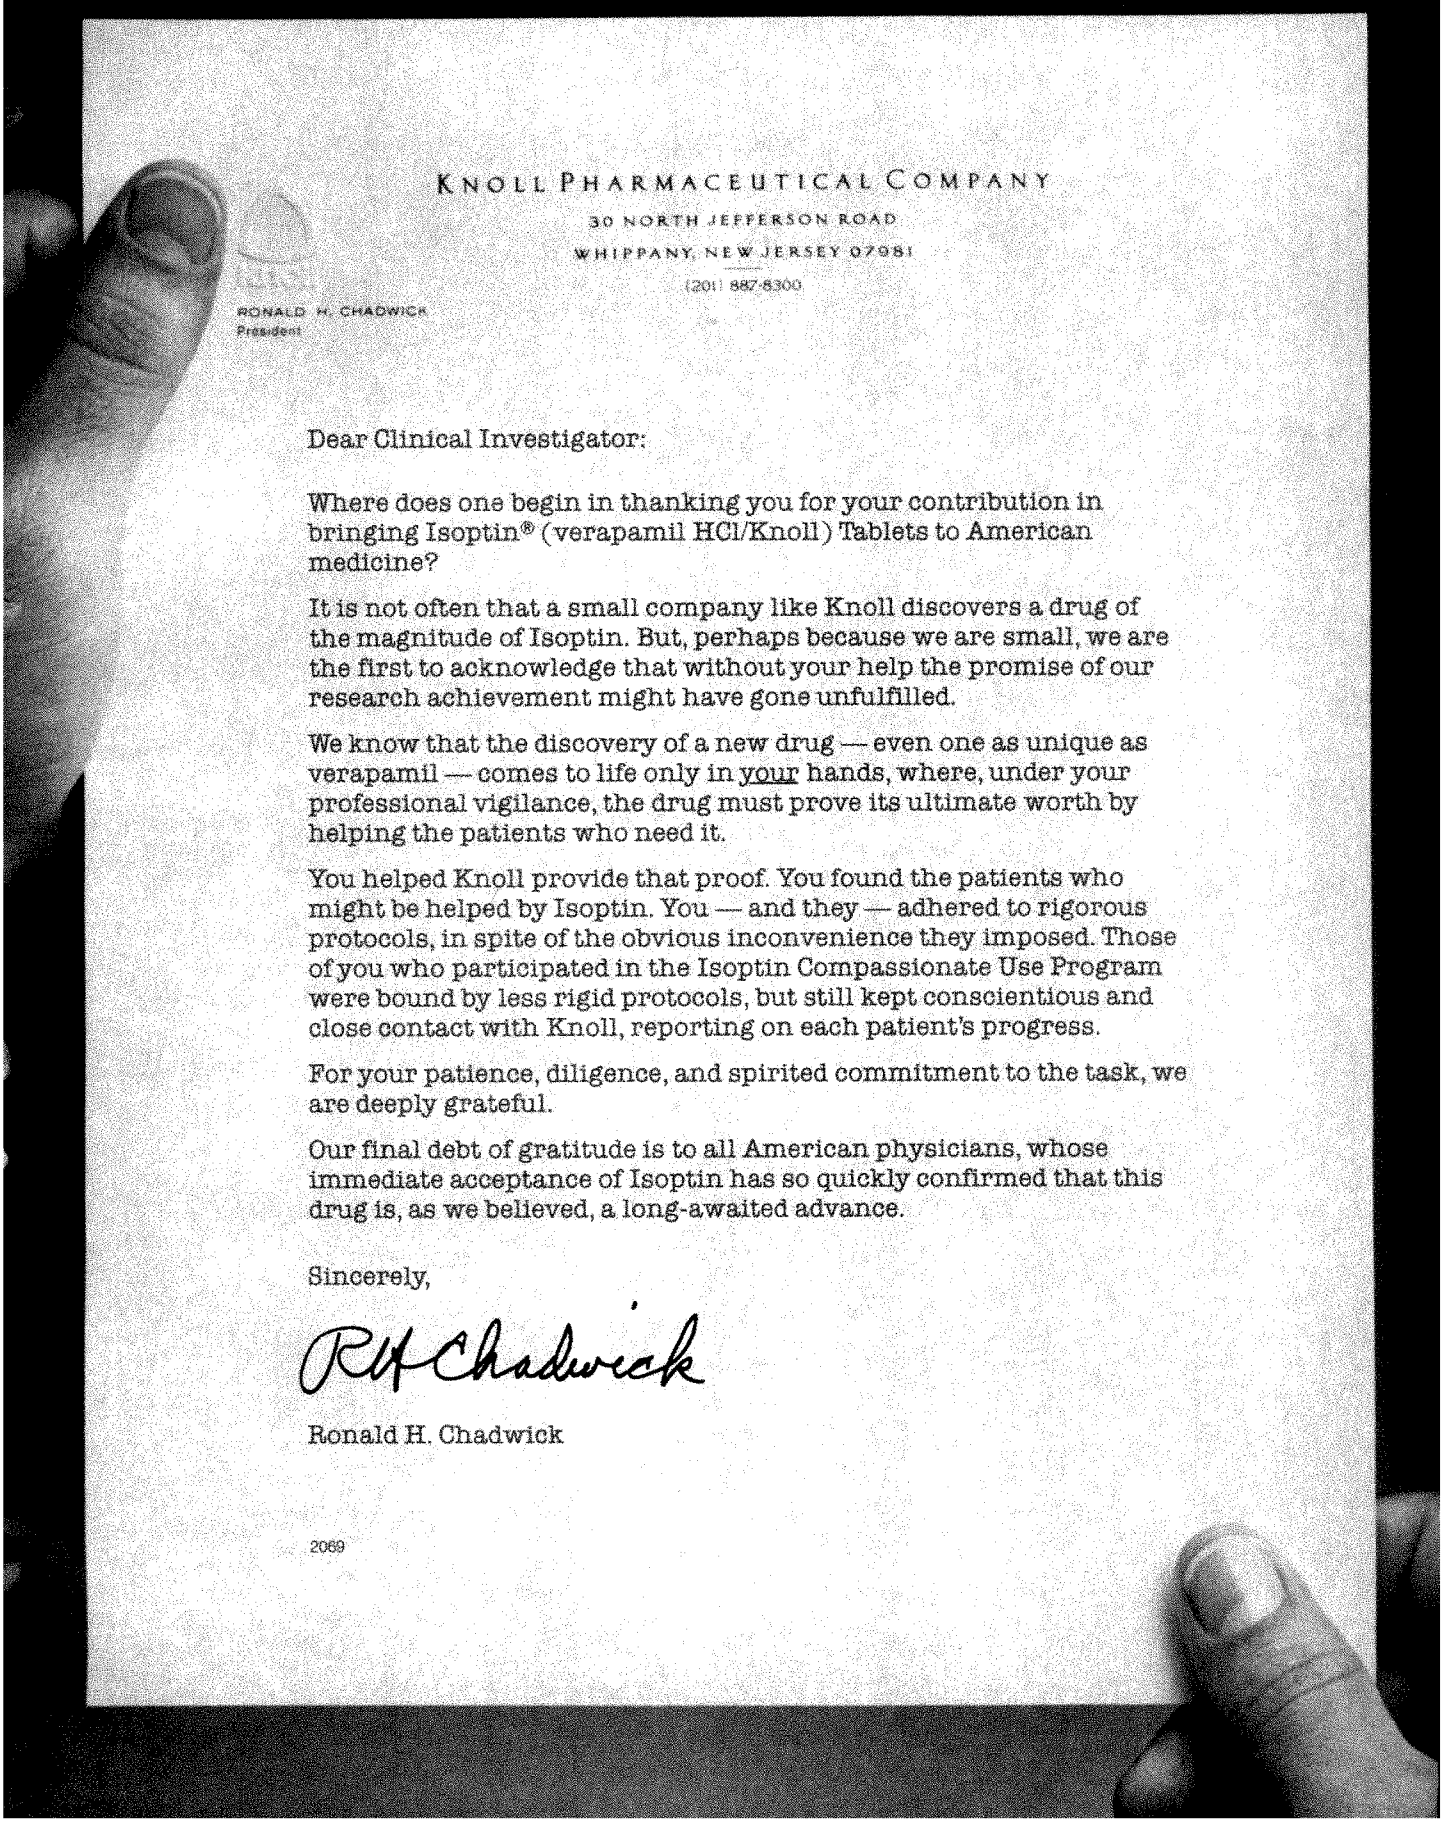
This thank-you letter is too important to be buried in a pile of mail.



KNOLL PHARMACEUTICAL COMPANY

30 NORTH JEFFERSON ROAD

WHIPPANY, NEW JERSEY 07981

(201) 887-8300

RONALD H. CHADWICK
President

Dear Clinical Investigator:

Where does one begin in thanking you for your contribution in bringing Isoptin® (verapamil HCl/Knoll) Tablets to American medicine?

It is not often that a small company like Knoll discovers a drug of the magnitude of Isoptin. But, perhaps because we are small, we are the first to acknowledge that without your help the promise of our research achievement might have gone unfulfilled.

We know that the discovery of a new drug — even one as unique as verapamil — comes to life only in your hands, where, under your professional vigilance, the drug must prove its ultimate worth by helping the patients who need it.

You helped Knoll provide that proof. You found the patients who might be helped by Isoptin. You — and they — adhered to rigorous protocols, in spite of the obvious inconvenience they imposed. Those of you who participated in the Isoptin Compassionate Use Program were bound by less rigid protocols, but still kept conscientious and close contact with Knoll, reporting on each patient's progress.

For your patience, diligence, and spirited commitment to the task, we are deeply grateful.

Our final debt of gratitude is to all American physicians, whose immediate acceptance of Isoptin has so quickly confirmed that this drug is, as we believed, a long-awaited advance.

Sincerely,

RH Chadwick

Ronald H. Chadwick

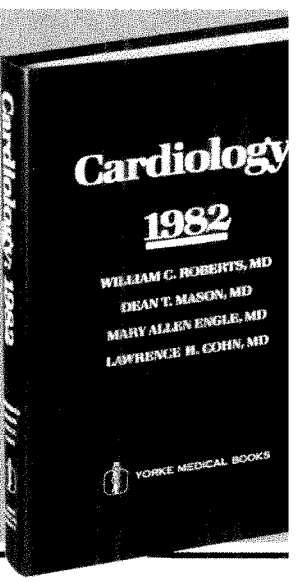
ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable style fundamental and new information essential to unders current thinking on managing cardiovascular disease. It what's new with well-established data, arming the reader spective on the field which is simply unavailable elsewher use of illustrations and original tables condenses valuable into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of c
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains wh average physician may be obscure....a treasure house of 198 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal o Medicine, September, 198

"This is an excellent book, very well organized and written...s on the shelf of the library, cardiologist, and internist."

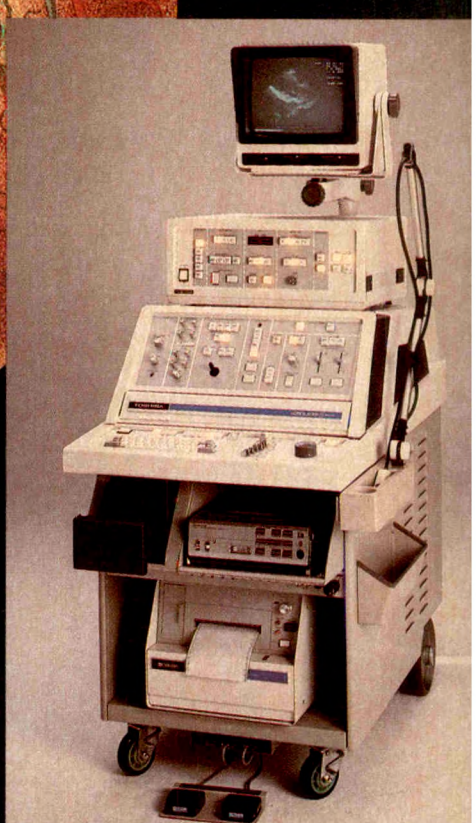
Clinical versatility redefined.



The TOSHIBA SSH-40A Cardiac Phased Array Sector Scanner brings new meaning to clinical versatility. The SSH-40A offers superb image quality, extensive computational capability, and the ability to perform a wide variety of examinations. It incorporates advanced technological developments such as: Automatic Electronic Focusing, the field's first Two Dimensional Gate Array Doppler, and a very powerful on-board computer. From neonates to adults, from standard views to special flow studies, from simple imaging to functional calculations, the new SSH-40A is truly a new generation in phased array.

You expect new innovations from TOSHIBA. We're the Total Imaging Company with over 12,000 ultrasound scanners in use throughout the world.

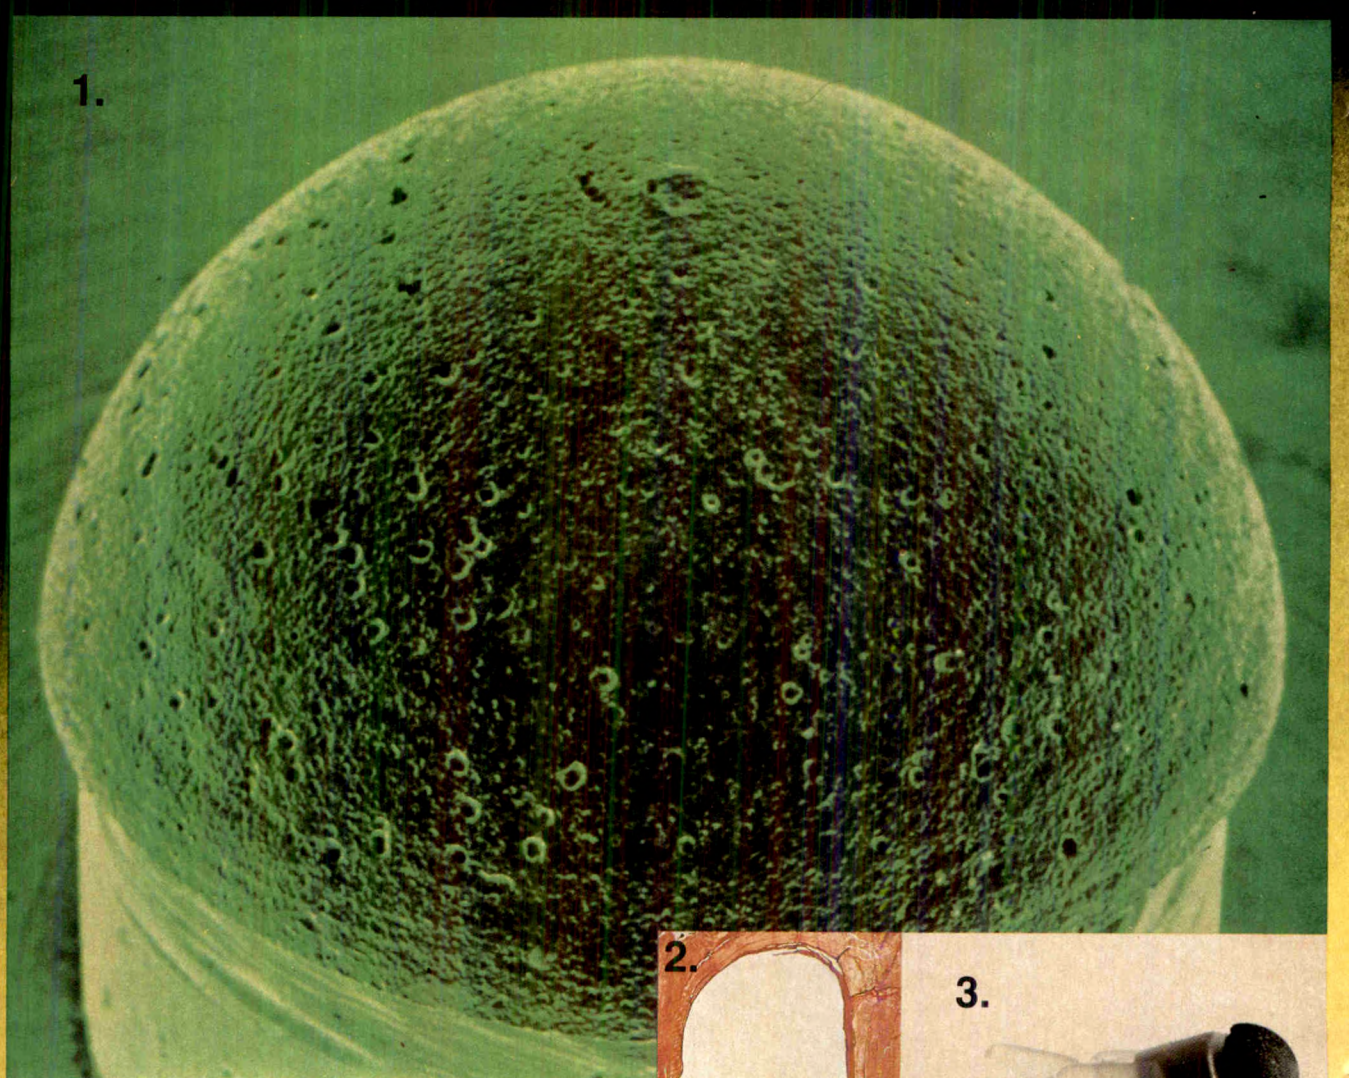
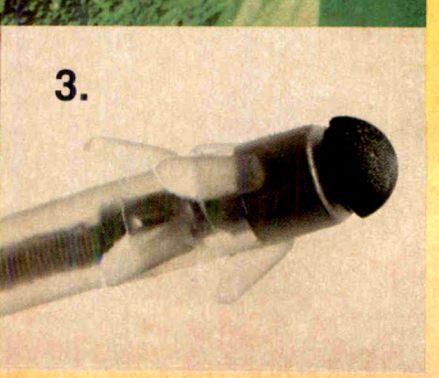
We are convinced... that carbon is far more





1. The surface structure of the vitreous carbon tip.
2. The thin fibrotic capsule formed by a carbon tip.
3. The 412S with tines for secure anchorage in the right auricle or in the ventricle.

precious than platinum.

The Siemens-Elema ACE™ (**A**ctivated **C**arbon **E**lectrode) carbon tip pacing leads utilize the unique properties of vitreous carbon.

We are the sole manufacturer of this material which, thanks to minor tissue reaction, gives significantly low polarization voltages.

Clinical experience has shown low chronic thresholds, which reduce the risk of exit block.

Pacemaker longevity can be increased through reduction of output energy, consistent with the reduced threshold of the ACE™ electrode.

82216

CAUTION:
Read Physicians Product Manual (ME 372/5713.406) for proper implantation procedures and possible complications.
POSSIBLE COMPLICATIONS
An implanted pacemaker electrode is in direct contact with the myocardium. Equipment operating on alternating current can present a risk of causing fibrillation, if it is not satisfactorily grounded, or if it is faulty. Even battery-operated instruments connected to the electrode can be dangerous, if they are in contact with the above-mentioned equipment.
The following are examples of other complications that can arise:
• Intermittent or continuous "exit block", or detection problems, caused, for example, by dislodgement of the tip of the electrode, perforation of the myocardium, or insulation defects.
• Infection at the point of connection to the vein, which can require surgical treatment.

DIGITALIS TOXICITY
– and how to avoid it in CHF:
Graphic Rep

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF furosemide

Every CHF patient on a digitalis-diuretic regimen runs the risk of digitalis toxicity.

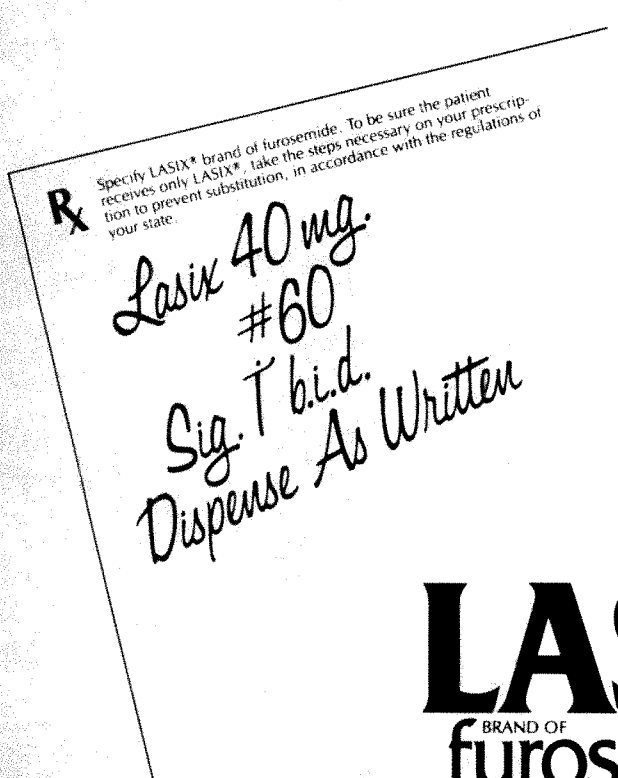
But many patients with impaired renal function are particularly vulnerable because their condition may predispose them to a toxic accumulation of digoxin.

These include the diabetic. The geriatric patient. The patient with renal disease. And the patient with advanced CHF who suffers from hepatic as well as renal complications.

Add to this group the patient on multiple medications with possible drug interactions.

Conditions like these that increase the risk of digitalis toxicity are generally outside the physician's control. But two of the most important *preventive* measures which are not outside the physician's control are precise titration of digitalis, *and the consistent use of one diuretic.*

As to the first, the narrow therapeutic-to-toxic range of digitalis is well known and requires no elaboration.



Naturally, increased renal problems necessitate increased vigilance to any signs of toxicity.

Why the patient should be maintained on LASIX®

The second precaution is the unvarying use of a single diuretic for a given patient (consistent with proper potassium balance). Thus, if the choice is LASIX®—as it is in most successfully managed CHF cases—the logic behind it is beyond debate. LASIX® is the only diuretic for CHF whose effectiveness has been confirmed in no fewer than 6,000 published papers...which offers the most complete range of dosage forms and strengths for precise titration.., and is the most widely available brand of furosemide for filling or refilling your prescription anywhere in the United States. In fact, according to a 1980 nationwide survey,[1] office-based physicians affirmed their confidence in LASIX® by naming it as the medication they prescribe most frequently in office practice.

Protect your LASIX® prescription: prevent substitution

When you prescribe LASIX®, write the phrase "Do not substitute," or whatever your state requires on the prescription.

If you are in doubt about a particular generic furosemide, call the offices of the Food and Drug Administration's Bureau of Drugs, Consumer and Professional Relations staff at 301-443-1016.

Reference: 1. Koch H: Drugs most frequently used in office-based practice: National Ambulatory Medical Care Survey, 1980, Vital and Health Statistics of the Nat Ctr for Health Statistics, No. 78 (May 12) 1982.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

LASIX®

TABLETS: 20, 40 & 80 mg

BRAND OF furosemide

The diuretic of choice for the digitalized patient.

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2.4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCK2

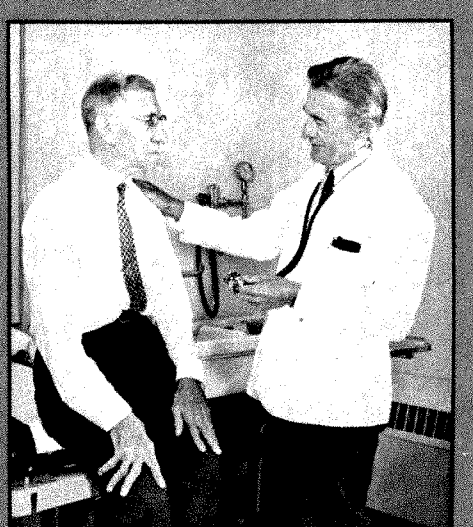
Vascular conditions can present severe diagnostic challenges to even the most experienced clinician.



Vascular conditions such as pulmonary embolism and aortic dissection are often difficult to diagnose. That's why you'll find this title in the Cardiovascular Clinics to be particularly valuable.

Volume 13, Number 2 Cardiovascular Clinics

CLINICAL VASCULAR DISEASE

You'll find wide ranging coverage of virtually every common and uncommon manifestation of peripheral and occlusive vascular disease encountered in a clinical situation. Practical diagnostic and therapeutic principles are stressed in every chapter.

Of particular interest:
- cerebrovascular disease
- surgical treatment of occlusive arterial disease
- balloon angioplasty
- antithrombotic therapy
- diagnosis of leg ulcer
- differential diagnosis of edema
- aneurysmal disease.

Guest Editor: **John A. Spittell, Jr.**, MD, FACP, FACC, Mary Lowell Leary Professor of Medicine, Mayo Medical School; Consultant, Cardiovascular Diseases and Internal Medicine, Mayo Clinic; with 22 other contributors. About 330 pp., 155 ill. Ready Jan. 1983. About $45.00.

Contents: Principles of Conservative Treatment of Occlusive Arterial Disease • Chronic Occlusive Arterial Disease of the Lower Extremities • Principles and Techniques of Occlusive Arterial Disease of the Lower Extremities • Acute Arterial Occlusion • Occlusive Arterial Disease in the Upper Extremity • Vasospastic Disorders • Aneurysmal Disease • Aortic Dissection • Acute Venous Thrombosis • Chronic Venous Insufficiency • Pulmonary Embolism • Differential Diagnosis of Leg Ulcer • Occlusive Cerebral Arterial Disease • Occlusive Renovascular Disease • A Perspective of Percutaneous Transluminal Angioplasty • The Vasculitides • Lymphedema • Differential Diagnosis of Edema of the Lower Extremities • Antithrombotic Therapy.

Also of Interest:

Controversies in Coronary Artery Disease, Cardiovascular Clinics, Volume 13, Number 1

This fascinating volume offers the opinions of leading medical authorities on 18 current and controversial issues relating to coronary artery disease. Although the experts may disagree, each point of view is based on sound medical facts.

Guest Editor: **Shahbudin H. Rahimtoola, MD,** Professor of Medicine, Chief Section of Medicine Cardiology, University of Southern California, Los Angeles, Calif.; with 38 other contributors. 367 pp. 140 ill. September 1982. $45.00.

A Guide to Cardiac Pacemakers

In one single, lavishly illustrated source, **A Guide to Cardiac Pacemakers** answers your many questions concerning the profusion of pacemakers available today. It covers all the major topics, including operational variations, functional time variations, manufacturers and their models, and radiologic identification of a pacemaker in a patient.

Edited by **Dryden Morse, MD; Robert M. Steiner, MD;** and **Victor Parsonnet, MD.** About 380 pp., 400 ill. Ready April 1983. About $65.00.

Cardiac Surgery, Cardiovascular Clinics, Volume 12, Number 3

In this outstanding new book, leading authorities discuss in depth the topics that are of vital concern to cardiologists and cardiovascular surgeons. They offer you practice-applicable advice on which forms of cardiac disease can be remedied surgically, how successfully, and with what sequelae.

Guest Editor: **Dwight C. McGoon,** MD, Professor of Surgery and Cardiology, Mayo Clinic, Rochester, Minnesota; with 45 other contributors. 242 pp. Illustd. January 1982. $40.00.

The Editor-in-Chief of the Cardiovascular Clinics is **Albert N. Brest,** MD.

I would like to receive the indicated books on 30-day approval.

In Holter studies...

An office-based system gives you the clinical data you're used to getting...without specially-trained operators.

After more than six years of development and rigorous clinical evaluation, a microcomputer based system called AEGIS™ is now available for ambulatory monitoring.

AEGIS has been designed to analyze in real time: ventricular ectopic beats (VEB), ventricular couplets (VC), ventricular tachycardia (VT), supraventricular premature beats (SVPB), and supraventricular tachycardia (SVT). Missed beats, marked pauses, sustained ventricular tachycardia, bradycardia and tachycardia are also differentiated by the system. When the 24-hour monitoring activity is completed, AEGIS provides the attending physician with a comprehensive summary report and confirming rhythm strips in minutes. The system is fully-automated so no specially-trained office staff is required, therefore turnaround time and cost of the procedure are substantially reduced.

Microcomputer Technology

The AEGIS Real Time Analyzer, a powerful 8 bit microcomputer system, combines the recording and analyzing activities in one unit that analyzes each heartbeat in real time, detecting, categorizing and counting arrhythmias as they actually occur. Because the analysis is in real time, the system is able to apply substantially more instructions per QRS than much more powerful computer systems operating at 60 to 240 times real time.

Accurate, consistent arrhythmia detection

AEGIS analyzes arrhythmias detecting departures in rate, rhythm and morphology from each patient's normal reference. The AEGIS computer can find and reference a patient's "normal" beat in less than two minutes even under a wide variety of difficult conditions such as chronic bigeminy, atrial fibrillation and bundle branch block. Furthermore, the "normal" reference beat is continually updated throughout the analysis period to account for changes in the position of the heart due to body movement.

Abnormal morphologies are detected via both feature extraction and template matching. (AEGIS is unique in its use of both methods of analysis.) When deviations exceed specified criteria, a morphology change is noted.

Rate, rhythm and morphology information is then applied to decision algorithms to determine the classification of each specific morphology change.

Overcoming problems caused by artifacts

To overcome the problem of artifacts and interference distorting information, AEGIS utilizes a series of highly refined classification algorithms developed from a data base of several hundred patients with a variety of morphologies, amplitudes and artifacts. A dual channel system, AEGIS also has the unique capability of being able to sense when artifacts are overwhelming the usefulness of information and to switch automatically to the other lead signal for processing.

Decision-making capability

The AEGIS 8 bit microcomputer system is augmented by an analog preprocessor which performs filtering, automatic gain control and QRS detection functions. Thus, the microcomputer has more time and memory available for real time decision making. In fact, AEGIS is able to apply many more computer cycles in this decision making than far more expensive scanner systems operating at high speeds.

Simplification

Because all analysis occurs within the compact 2.2 pound AEGIS Real Time Analyzer, the conventional high-speed scanner is replaced by a simple, automatic playback unit called a Report Generator. The need for a specially trained operator is eliminated.

Also eliminated are the dependence of reports on the qualitative perceptions of individuals and the inaccuracies or inconsistencies that result from operator variability and fatigue.

Advantages to the physician

The AEGIS System eliminates the turnaround time involved in using a scanning service—diagnostic results are printed in the physician's office, almost immediately.

All components have built-in quality control checks for rigorous verification of the system's integrity. Patient hook-up is identical to that of conventional Holter ECG recording systems; and, with minimal training, anyone can operate the Report Generator. Once begun, the printout process requires no operator attendance and rhythm strips as well as summary categorization reports are completed in minutes.

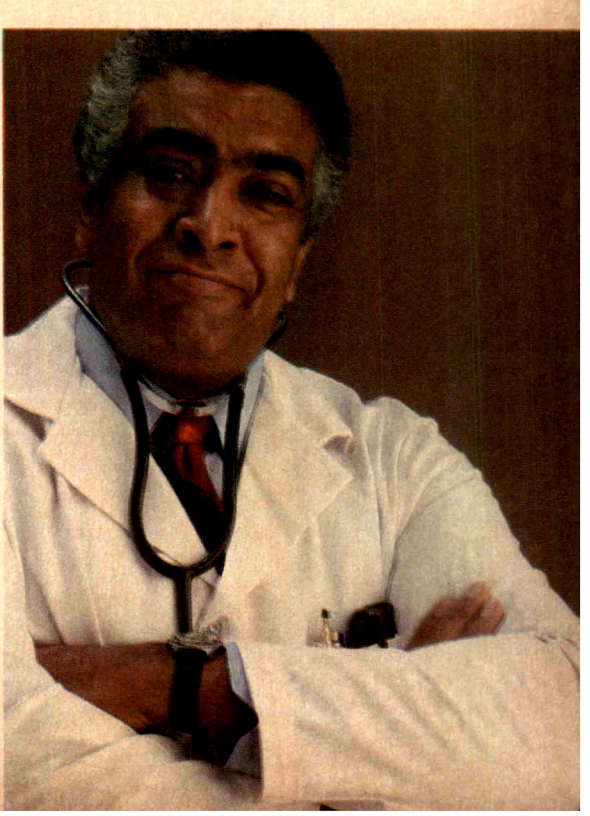
AEGIS can significantly reduce the cost of complete Holter analysis, and since it is a software based system, the physician can keep it updated as new technological advances are made. **AEGIS Ambulatory Monitoring Systems, Medical Concepts, Inc., 137 Gaither Drive, Mt. Laurel, New Jersey 08054.**

The patient-preferred once- or twice-a-day dual-control-mechanism 10-mEq wax-matrix slow-release potassium-chloride tablets

Klotrix®
(potassium chloride)
Slow-release tablets, 10 mEq

For patients who can't or won't take liquid KCl

It can change your patient's mind about KCl supplements!



Mead Johnson
PHARMACEUTICAL DIVISION

Please see following page for summary of prescribing information.

© 1982 Mead Johnson & Company • Evansville, Indiana 47721 USA

KLOTRIX®
(POTASSIUM CHLORIDE) SLOW-RELEASE TABLETS, 10 mEq

DESCRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS—BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ADVERSE REACTIONS Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose. One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.

Note: KLOTRIX® slow-release tablets must be swallowed whole and never crushed or chewed. Following release of the potassium chloride, the expended wax matrix, which is not absorbed, may be observed in the stool.

HOW SUPPLIED Bottles of 100, 1000, and Unit Dose cartons of 100.

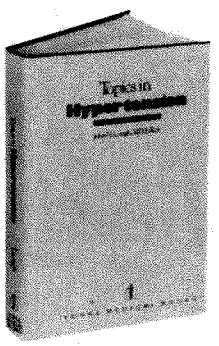
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

YORKE MEDICAL BOOKS AJCK2
Box C-757, Brooklyn, New York 11205

Send me, on approval, _____ copies of Laragh's TOPICS IN HYPERTENSION at $49.00. I will consult and read this new manual for 30 days, then remit only if I consider it a necessary addition to my library. Otherwise I will return it without further obligation.

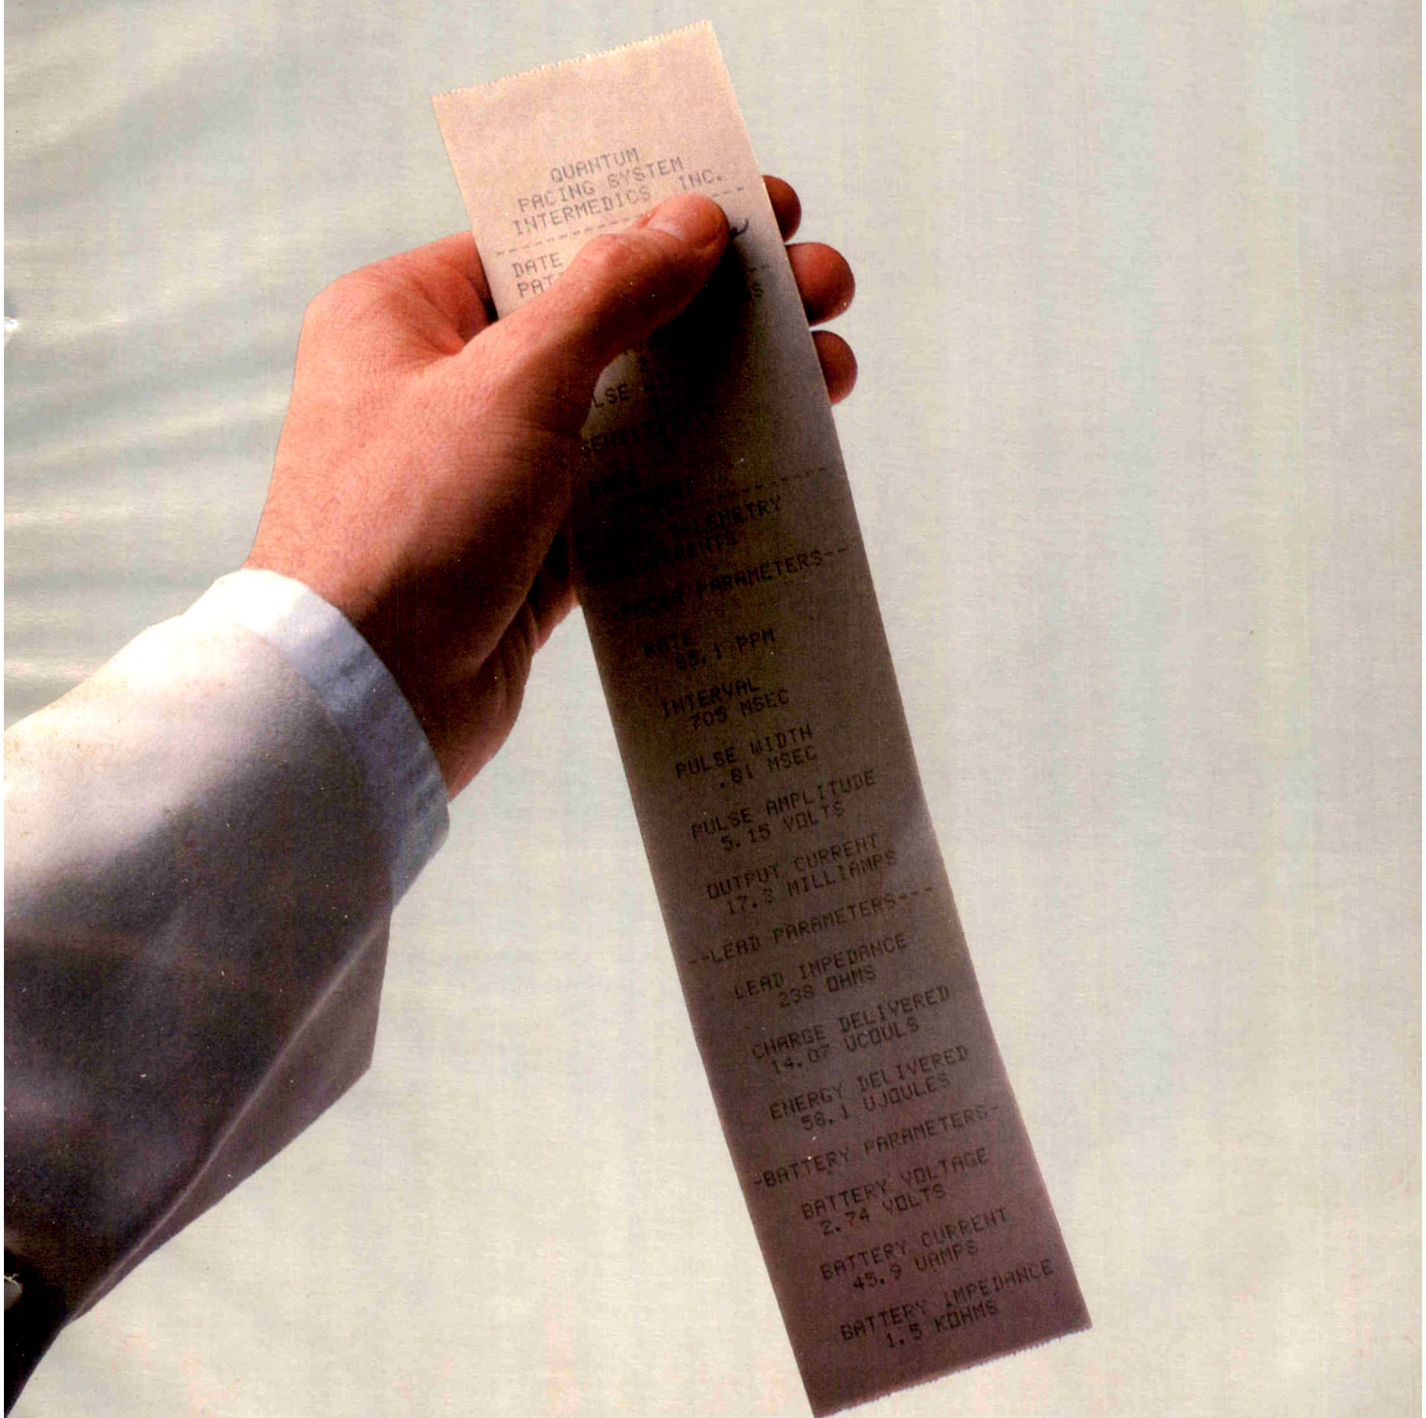
QUANTUM™

Intermedics Takes The Quantum Leap In Advanced Telemetry.



Better patient management with instant telemetry.

Quantum™ Gives You Actua
From Across The Room

More clinical data for better patient management.
Now physicians can quickly and easily get parametric data never before available from an implanted pacemaker. Whether your patient is in your office, at home, or across the country, Quantum gives you instant access to the condition of his pacing system via sophisticated telemetry transmission. The easy-to-learn, easy-to-use Quantum system requires no complicated electronic instrumentation. Just place the telemetry decoder over the patient's implanted pacemaker, press the measure key, and receive a digital display of pacing parameters. For remote monitoring the patient transmits the data to the decoder over the phone. It couldn't be simpler.

Printed records for accurate patient files.
The Quantum printer gives you an automatic printout of all measured data for permanent record keeping. Just place the decoder on the printer and press the button. Your files will be accurate and complete.

At the touch of a button you get:

- Pacemaker parameters: Rate, interval, pulse width, pulse amplitude, sensitivity setting and output current.
- Lead parameters: Impedance, charge delivered and energy delivered.
- Battery parameters: Voltage, current and impedance.

More information makes your clinical decisions easier.
Quantum provides you with more patient information than any other system available. It offers complete pacing data in the programmed mode or the magnet mode, at your option. With this information, you can confirm the pacemaker's

Pacemaker Operating Data Or Across The World.

operation, and determine what adjustments to make for best results. Patient management is easier and more comprehensive.

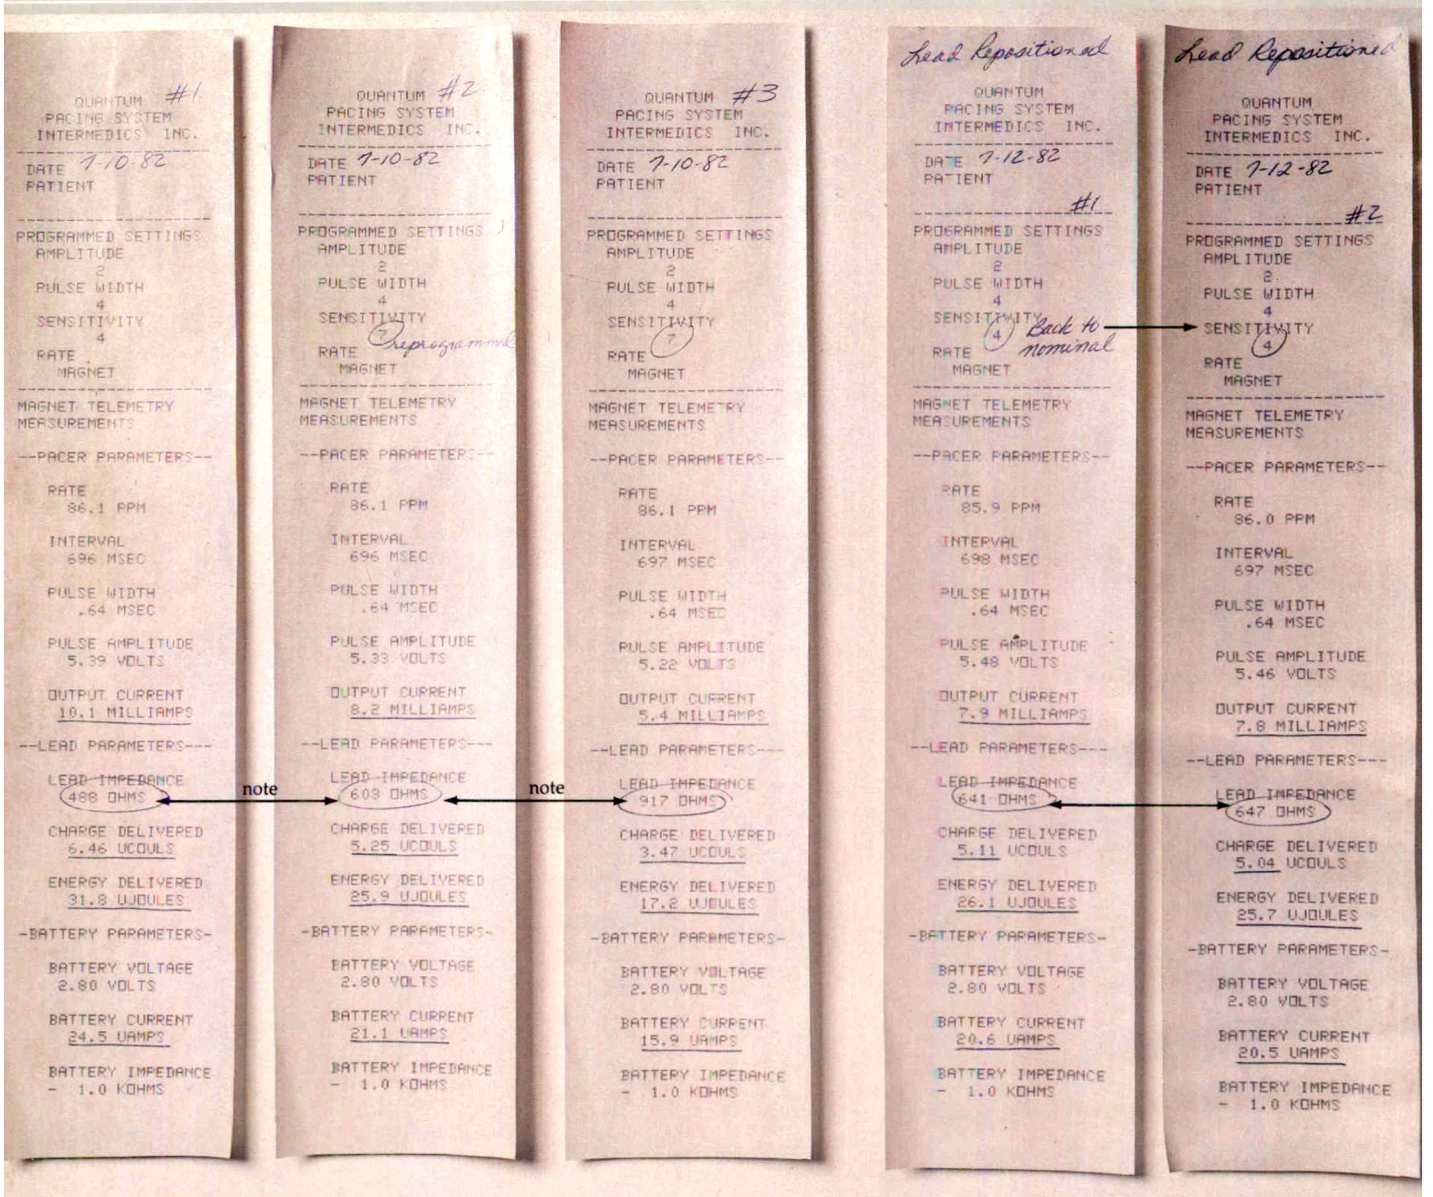
Expanded programming plus telemetry mean better patient management.

Quantum offers complete output tuning capabilities with programmable pulse amplitude and pulse width. This allows the physician to determine strength/duration curves non-invasively and to program the pacemaker to assure capture while conserving energy.

In addition to amplitude and pulse width, Quantum offers a full selection of pacing rates, sensitivities, and modes. These expanded programming options combined with Quantum's sophisticated telemetry, mean improved acute and chronic patient management.

Quantum is a complete pacing system, including a Decoder, Printer, Transmitter, Intermedics Programmer, and three pacemakers, representing the most sophisticated technology available today. Take the Quantum Leap to better patient management.

Quantum™ Telemetry Uncovers Lead Instability



An Actual Case History*

Patient: MALE
Age: 81 YEARS
Diagnosis: HEART BLOCK, BRADYCARDIA WITH EPISODES OF VENTRICULAR TACHYCARDIA
Indication for Pacing: ARRHYTHMIA (BRADYCARDIA) CONTROL

The patient received a Quantum model 253-09 pulse generator with a transvenous unipolar lead. Intra-operative fluoroscopy and threshold testing indicated acceptable lead position.

Eighteen hours post implant, telemetry measurements displayed lead parameters that fluctuated widely, as shown in three successive telemetry printouts. The patient was uncomfortable and while there was no evidence of loss of capture on the EKG, pacing and sensing were irregular. Further investigation and discussion between the cardiologist and implanting surgeon led to a decision to reposition the lead. Repositioning surgery was successful.

Normal pacing and sensing were observed after repositioning. Successive telemetry measurements showed stable lead parameters, verifying that a more satisfactory position had been achieved. The patient was discharged following good post-operative recovery and subsequent telemetry follow-up demonstrated chronic lead stability.

Lack of Effectiveness of Oral Mexiletine in Patients With Drug-Refractory Paroxysmal Sustained Ventricular Tachycardia

A Study Utilizing Programmed Stimulation

EDWIN V. PALILEO, MD, WILLIAM WELCH, MD, JULIE HOFF, Pharm D, BORIS STRASBERG, MD, ROBERT A. BAUERNFEIND, MD, STEVEN SWIRYN, MD, ALDO COELHO, MD, and KENNETH M. ROSEN, MD

Recent studies indicate that oral administration of mexiletine is useful in the therapy of recurrent ventricular tachycardia (VT). To further define the clinical usefulness of this drug, mexiletine was administered to 13 men and 4 women with a mean age ± standard deviation of 62 ± 8 years who had drug-refractory paroxysmal sustained VT associated with chronic ischemic heart disease in 14, valvular heart disease in 1, and primary myocardial disease in 1. One patient had no heart disease. All 17 patients had inducible sustained VT during the control electrophysiologic study and during serial electrophysiologic study on conventional drugs. Eleven patients tolerated a mean maximal daily dose of 1,073 ± 149 mg of mexiletine and underwent programmed ventricular stimulation; sustained VT was inducible in 10 patients and nonsustained VT in 1. In 10 patients with inducible sustained VT on mexiletine, the VT cycle length was longer during mexiletine therapy than during control (mean ± standard error of the mean, 342 ± 22 versus 268 ± 14 ms, respectively) ($p < 0.005$). Programmed stimulation was not possible in 1 patient with severe neurologic side effects and in 5 patients with mexiletine-related worsening of ventricular arrhythmia. Seven other patients had severe neurologic or gastrointestinal side effects, necessitating dose reduction in 5. This 47% incidence of noncardiovascular side effects is similar to that in previous reports, but the 29% incidence of arrhythmia potentiation by mexiletine is unexpectedly higher. Limited follow-up reveals recurrence of VT in 3 of 4 patients treated with oral mexiletine on a long-term basis. In conclusion, oral mexiletine does not appear useful in the therapy of patients with drug-refractory, paroxysmal sustained VT. In addition, its use is associated with a high incidence of adverse effects, cardiovascular (arrhythmic) and noncardiovascular, some of which can be serious and life-threatening.

During the last decade, major advances have been made in the understanding of recurrent sustained VT.[1,2] During the last 5 years, various electrophysiologic,[3,4] surgical,[5,6] and pacemaker[7,8] approaches to the therapy of recurrent sustained VT have evolved, reflecting not only advances in understanding, but also the difficulty in managing this clinical problem. The continuing development of multiple new antiarrhythmic drugs reflects major deficiencies in currently available drugs.

From the Section of Cardiology, Department of Medicine, Abraham Lincoln School of Medicine, University of Illinois College of Medicine and West Side Veterans Administration Medical Center, Chicago, Illinois. This study was supported in part by Institutional Training Grant HL 073787 and Research Grants HL 18794 and 23566 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, and by grants from the Eleanor B. Pillsbury Resident Trust Fund and the Bane Estate, Chicago, Illinois. Manuscript received March 9, 1982; revised manuscript received March 10, 1982, accepted May 13, 1982.

Address for reprints: Edwin V. Palileo, MD, Section of Cardiology, University of Illinois Hospital, PO Box 6998, Chicago, Illinois 60680.

One of these new drugs is mexiletine, a phenethanolamine compound chemically similar to lidocaine and possessing electrophysiologic properties which resemble lidocaine in some actions and quinidine in others.[9,10] Although clinical trials have demonstrated its effectiveness in ventricular arrhythmias associated with a variety of heart diseases,[11,12] its effectiveness in recurrent sustained VT not associated with acute myocardial infarction was not known until recently.[13,14] Ruskin et al.[13] demonstrated its effectiveness as a single drug in 9 patients and as part of a combination regimen in 4 of 25 patients resuscitated from out-of-hospital cardiac arrest due to VT or ventricular fibrillation, utilizing the technique of serial electrophysiologic and pharmacologic testing. The same investigators,[14] utilizing serial electrophysiologic testing, reported that in 17 of 41 patients with recurrent ventricular arrhythmias resistant to conventional drugs, mexiletine suppressed ventricular arrhythmia during acute administration. Encouraged by these reports indicating that mexiletine

is useful in recurrent sustained VT and to further define its clinical usefulness, we systematically evaluated oral mexiletine in a group of patients with paroxysmal sustained VT which was refractory to conventional drugs.

Methods

Study patients: All patients were referred to the University of Illinois Hospital or the West Side Veterans Administration Medical Center for evaluation and management of paroxysmal sustained VT. Criteria for inclusion in the study were as follows: (1) electrocardiographically documented paroxysmal sustained VT; (2) induction of sustained VT during control electrophysiologic study; and (3) demonstration of refractoriness to conventional antiarrhythmic drugs, defined as the continued ability to have electrically inducible or spontaneously occurring VT while on adequate therapy (with therapeutic serum drug levels) with conventional drugs, or the inability to tolerate therapeutic doses of conventional drugs. Patients with recent myocardial infarction (within 6 weeks) were excluded.

Clinical characteristics: The presence or absence as well as the nature and severity of heart disease were evaluated by history, physical examination, chest x-ray, resting and stress electrocardiography, echocardiography, radionuclide angiography, and cardiac catheterization as clinically indicated.

Control electrophysiologic study: These studies were performed with the patients in the nonsedated postabsorptive state, after informed written consent had been obtained and after all antiarrhythmic drugs had been discontinued for at least 5 drug half-lives. Multipolar electrode catheters with a 1 cm interelectrode distance were inserted either percutaneously or through venesection and were positioned at the high lateral right atrium, the right atrioventricular junction at the region of the His bundle, and the apex of the right ventricle. Intracavity bipolar electrograms were filtered between 30 and 500 Hz and displayed simultaneously with surface electrocardiographic leads I, II, III, and V_1 on a multichannel oscilloscope and recorded at paper speeds of 100 and 250 mm/s utilizing a fiberoptic photographic recorder (Electronics for Medicine, Minneapolis). These data were also stored on magnetic tape utilizing a multichannel, frequency modulation magnetic tape recorder (Honeywell-Electronics for Medicine) for future retrieval.

Cardiac stimulation was provided by an optically isolated, digital programmable stimulator (M. Bloom, Narbeth, Pennsylvania) which delivered rectangular pulses of 2 ms duration and current strength of approximately twice diastolic threshold.

The following stimulation protocol was used in all studies: (1) atrial incremental pacing from a rate just above the sinus rate to a rate producing second-degree atrioventricular block; (2) atrial extrastimulus testing coupled to sinus rhythm and to multiple atrial driven rhythms at cycle lengths shorter than sinus cycle length; (3) a single ventricular extrastimulus coupled to a ventricular driven rhythm at cycle lengths of 450 to 600 ms; (4) double ventricular extrastimuli (V_1–V_2–V_3) coupled to a ventricular driven rhythm at cycle lengths of 450 to 600 ms; (5) bursts of rapid ventricular pacing from rates of 120 to 250 beats/min.

These pacing modalities were performed in sequence until VT was induced, ventricular refractoriness was reached, or the maximal pacing rate was achieved. When induced VT was hemodynamically stable, termination by the extrastimulus technique was attempted. Otherwise, bursts of rapid ventricular pacing at progressively increasing rates above the tachycardia rate was utilized for termination of tachycardia. In patients who exhibited hemodynamic deterioration from prolonged VT due to difficult termination, acceleration of VT during attempts at termination, or deterioration to ventricular flutter or fibrillation, external direct current cardioversion was performed immediately. Use of electrical cardioversion or extreme difficulty in pacing conversion of induced VT precluded completion of the stimulation protocol on any given day.

Serial electrophysiologic testing: When sustained VT could be reliably induced in the control state, a catheter introduced from an arm vein was left indwelling with the distal pair of electrodes located at the apex of the right ventricle. The ventricular stimulation protocol was then repeated after intravenous loading with procainamide (1.0 to 1.5 g total) on the first day and after 4 oral doses of quinidine sulfate (1,600 mg total) and disopyramide phosphate (1,200 mg total) on the second and third days of the serial study, respectively.

Drug responses were defined as successful if sustained VT was not inducible or was converted to nonsustained VT. A response was unsuccessful if sustained VT was still inducible on the drug. An unsuccessful but favorable response was defined as inducible sustained VT, with a significant increase in the tachycardia cycle length associated with a stable hemodynamic state and allowing pacing termination of the tachycardia. Sustained VT was defined as VT lasting longer than 30 seconds and requiring electrical or pharmacologic intervention for termination. Nonsustained VT was defined as VT that spontaneously terminated after 5 beats and before 30 seconds.

Mexiletine protocol: After demonstration of refractoriness to conventional drugs, oral mexiletine was administered at a dose of 200 mg every 8 hours on the first day. If well tolerated, the dose was increased to 300 mg every 8 hours on the second day, and to 400 mg every 8 hours on the third day. In patients who had intolerable neurologic side effects, the dose was reduced until the side effects disappeared or were decreased to tolerable severity. In patients who exhibited a definite worsening of VT before the scheduled electrophysiologic testing, the drug was discontinued and no further testing was carried out. In patients who had no worsening of VT and who tolerated the drug well (in some, after dose reduction), programmed ventricular stimulation was performed while the patient was receiving the highest tolerated dose of mexiletine. In most patients the insertion of a new electrode catheter for testing mexiletine was necessary.

Chronic mexiletine therapy: In patients demonstrating an unsuccessful response to mexiletine, other therapeutic modalities were pursued. In patients demonstrating a successful response to mexiletine, chronic therapy was instituted. In some patients in whom an unsuccessful but favorable response to mexiletine was demonstrated and in whom there were no better therapeutic alternatives, chronic oral mexiletine therapy was also instituted. The dosage used for long-term therapy was identical to the tested dosage for each patient.

Follow-up: Patients on chronic oral mexiletine therapy were followed up in an outpatient arrhythmia clinic on a periodic basis, utilizing repeated ambulatory electrocardiographic recording or transtelephonic transmitters to monitor recurrence of VT.

Analysis of data: A standard Student's t test was used to test the significance of groups of paired data.

TABLE I Clinical Characteristics

Case	Age (yr) & Sex	Diagnosis	Cardio-megaly	WMA	LVEF	Arrhythmia	Cardio-version
1	67M	CIHD	+	+	0.31	VT	+
2	64M	CIHD	+	+	0.25	VT	−
3	70M	CIHD	−	+	0.24	VT	−
4	61M	CIHD	+	+	0.23	VT	−

CIHD = chronic ischemic heart disease; LVEF = left ventricular ejection fraction; OHD = organic heart disease; PMD = primary myocardial disease; VHD = valvular heart disease; VT = ventricular tachycardia; WMA = wall motion abnormality.

Results

Seventeen patients satisfied all inclusion criteria (Table I). There were 13 men and 4 women, aged 51 to 75 years (mean 62 ± 8). (Results are reported as mean ± standard deviation unless stated otherwise.) Sixteen patients had organic heart disease (14 chronic ischemic heart disease, 1 valvular heart disease, and 1 primary cardiomyopathy). One patient had no evidence of structural heart disease. All 16 patients with organic heart disease demonstrated left ventricular wall motion abnormalities on contrast angiography (13 patients), radionuclide angiography (9 patients), or both. Left ventricular ejection fraction ranged from 0.10 to 0.51 (mean 0.29 ± 0.10). In 10 patients with ischemic heart disease who underwent coronary arteriography, significant stenosis (greater than 50 percent narrowing of luminal diameter) was demonstrated in 2 to 3 coronary arteries per patient (mean 2.8 ± 0.4).

Ventricular tachycardia necessitated hospitalization in all patients and required external direct current

TABLE II Electrophysiologic Characteristics

	Control Study				Study on Mexiletine					
Case	Inducible Rhythm	VTCL (ms)	Initiation	Termination	Inducible Rhythm	VTCL (ms)	Initiation	Termination	Dose (mg/day)	Side Effects

* Patients who received long-term treatment with oral mexiletine.

CV = cardioversion; NSVT = nonsustained ventricular tachycardia; NT = not tested; RVP = bursts of rapid ventricular pacing; S_2 S_3 = double premature stimulation; Spont. = spontaneous; Sus. = sustained; V_1 V_2 = single extrastimulus; V_1 V_2 V_3 = double extrastimulus; VTCL = ventricular tachycardia cycle length.

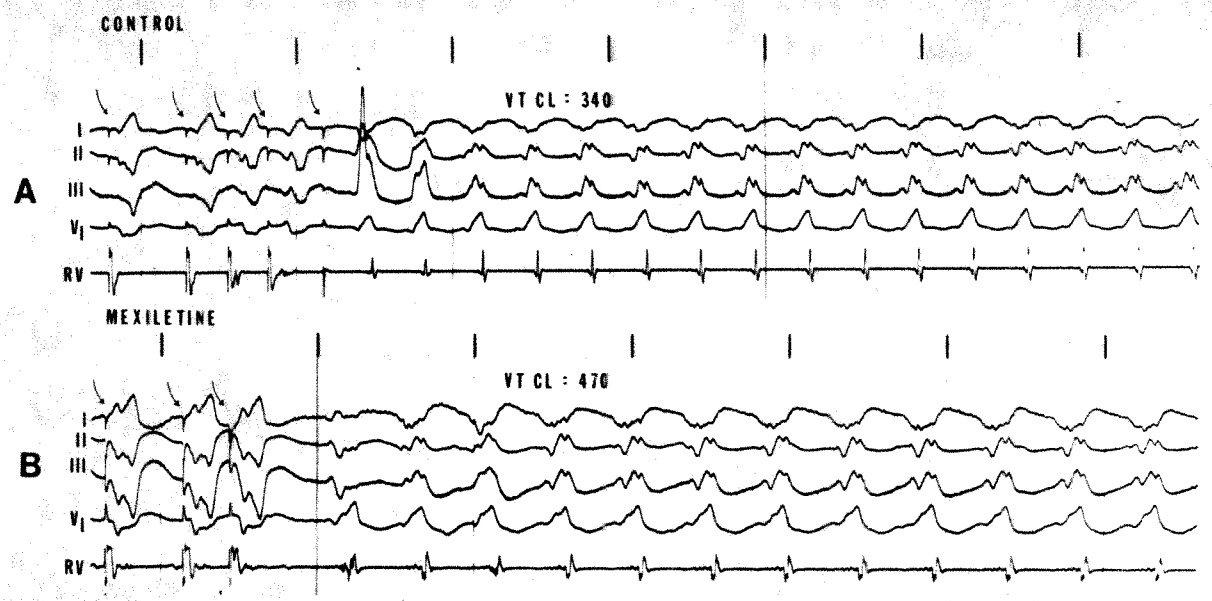

FIGURE 1. An unsuccessful response to mexiletine therapy. Electrocardiographic leads I, II, III, and V_1 and right ventricular electrograms (RV) are shown. VT CL = ventricular tachycardia cycle length. **Arrows** indicate ventricular pacing spikes. **Panel A,** during control study the right ventricle is paced for 8 beats at a cycle length of 500 ms, followed by ventricular extrastimuli at an S_1–S_2 interval of 270 ms, S_2–S_3 of 260 ms, and S_3–S_4 of 300 ms. (The third extrastimulus failed to capture the ventricle.) Sustained VT is induced at a cycle length of 340 ms. **Panel B,** during mexiletine therapy at a total daily dose of 1,200 mg, the right ventricle is paced at a cycle length of 500 ms. After an extrastimulus at an S_1–S_2 interval of 300 ms, sustained VT at a cycle length of 470 ms is induced. Time lines are at 1 second intervals.

cardioversion for termination in 10. The cycle length of spontaneously occurring VT was 275 to 462 ms (mean 359 ± 50) (heart rates 130 to 220 beats/min, mean 167 ± 27).

Control electrophysiologic study (Table II): All patients had inducible sustained VT during the control electrophysiologic study (by study design). VT was induced by double ventricular extrastimulation in 13 patients and by rapid ventricular pacing in 4. Termination was by premature stimulation in 1, by bursts of rapid ventricular pacing in 8, and by external direct current cardioversion in 8. The cycle length of induced VT was 200 to 400 ms (mean 291 ± 55).

Serial electrophysiologic study: All patients underwent serial electrophysiologic testing with conventional drugs, and some patients with other investigational drugs, before mexiletine therapy. These studies demonstrated unsuccessful responses in 3 to 6 separately tested drugs per patient (mean 4 ± 1 drugs per patient) (by study design).

Mexiletine therapy (Table II): Oral mexiletine was administered according to the protocol, with an achieved maximal tolerated daily dose of 900 to 1,200 mg (mean 1,073 ± 149) in 11 patients, allowing evaluation by programmed ventricular stimulation after 1 to 9 days (mean 4 ± 2) of mexiletine therapy. In 6 patients, mexiletine could not be tested by the programmed ventricular stimulation technique (see later). Programmed ventricular stimulation during mexiletine therapy in 11 patients resulted in induction of sustained VT in 10 patients (Fig. 1) and nonsustained VT in one (Fig. 2). Induction was by single and double ventricular extrastimulation in 9 and rapid ventricular pacing in 2. Termination was spontaneous in 1 (the patient with nonsustained VT on mexiletine therapy), by premature stimulation in 1, by bursts of rapid ventricular pacing in 7, and by external direct current cardioversion in 2 patients. In 10 patients with an unsuccessful response to mexiletine, the cycle length of induced VT while on mexiletine was 250 to 470 ms (mean ± standard error of the mean [SEM] 342 ± 22). This was significantly longer than the cycle length of induced VT during the control state, which was 200 to 300 ms (mean ± SEM 268 ± 14) ($p < 0.005$) (Fig. 3). This increase in the tachycardia cycle length allowed termination of pacing in most patients and reduced the necessity for external direct current cardioversion from 7 occasions during the control study to 2 occasions during the mexiletine study.

Mexiletine side effects (Table II): In 6 of the 17 patients, programmed ventricular stimulation during mexiletine therapy was not possible. In 1 patient, mexiletine administration was stopped because of intolerable neurologic side effects after two 200 mg doses. In 5 patients (29 percent), worsening of VT during mexiletine therapy prevented further administration. Sustained VT occurred spontaneously after 6 days of therapy at 900 mg/day in the first patient, and after 2 days at 900 mg/day in the second. The third patient had spontaneous VT requiring external direct current cardioversion after two 200 mg doses of mexiletine, while the fourth patient had multiple episodes of sustained VT requiring repeated pacing conversion and external direct current cardioversion after two 100 mg doses (the

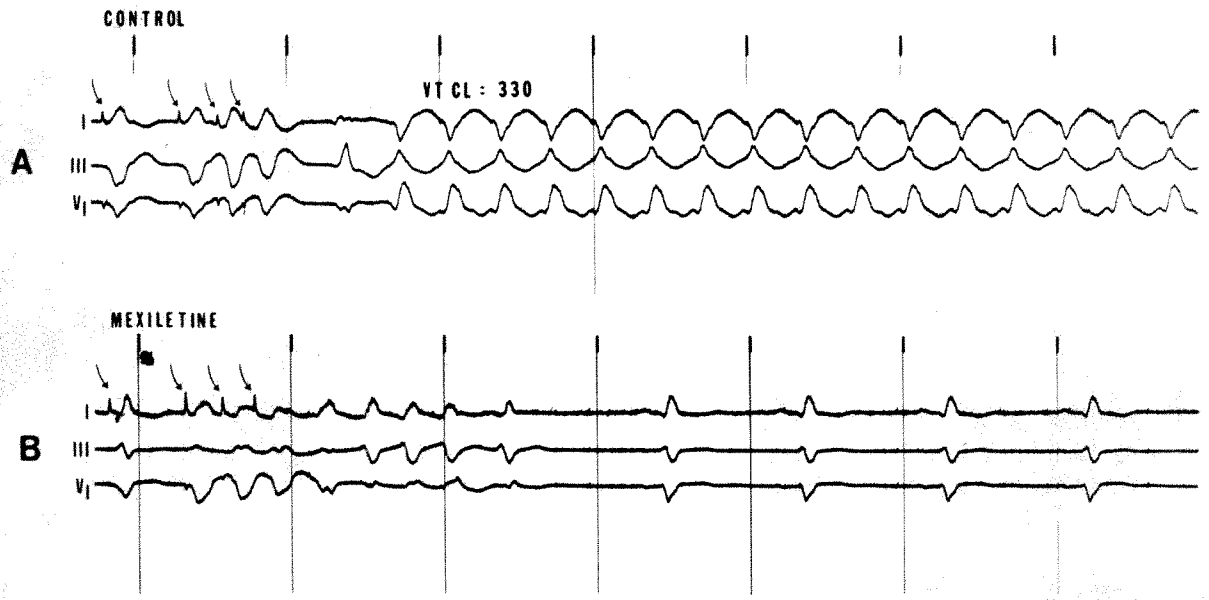

FIGURE 2. A successful response to mexiletine. Arrangement, abbreviations, and symbols as in Figure 1. **Panel A,** during control study the right ventricle is paced for 8 beats at a cycle length of 500 ms, followed by 2 extrastimuli at an S_1–S_2 interval of 250 ms and an S_2–S_3 of 170 ms. Sustained VT is induced at a cycle length of 330 ms. **Panel B,** during mexiletine therapy at a total daily dose of 1,200 mg, the right ventricle is paced at a cycle length of 500 ms followed by 2 extrastimuli at an S_1–S_2 interval of 240 ms and S_2–S_3 of 210 ms. A maximum of 5 beats of nonsustained VT is induced.

lower initial dose in this patient reflects severe adverse experience with previous antiarrhythmic therapy).

In the fifth patient, torsade de pointes was observed for the first time after two 200 mg doses of mexiletine, requiring multiple external direct current cardioversion (Fig. 4).

In each of these 5 patients, the change in pattern of ventricular dysrhythmia was striking, suggesting that mexiletine potentiated VT. These were considered serious and life-threatening adverse effects of mexiletine therapy. In 7 other patients, less serious but incapacitating side effects (neurologic in 6 and gastrointestinal in 1) were observed. Reduction of the mexiletine dose was necessary before serial electrophysiologic testing in 5 of these patients.

Follow-up: In 13 patients, alternative forms of therapy were pursued. The patient who had a successful response to mexiletine was discharged on chronic oral mexiletine therapy at the tested dose. After 2 weeks of therapy, spontaneous sustained VT recurred, requiring hospitalization and external direct current cardioversion. This patient eventually underwent ventricular aneurysmectomy and endocardial resection.

In three patients who did not have other alternate therapy, and who demonstrated an unsuccessful but favorable response to mexiletine, chronic mexiletine therapy was instituted at the tested dose. After 6 to 15 months (mean 10 ± 5) of follow up, one patient has done well without any recurrence (6 months) while two have had multiple recurrence of sustained and usually self-terminating VT, within one to 16 weeks of therapy. Both patients have required hospitalization for recurrent VT.

Discussion

Significant advances in understanding recurrent sustained VT have been made in the last decade.[1,2] Although various electrophysiologic and pharmacologic,[3,4] surgical,[5,6] and pacemaker[7,8] approaches have evolved in the last 5 years, the therapy of recurrent VT remains

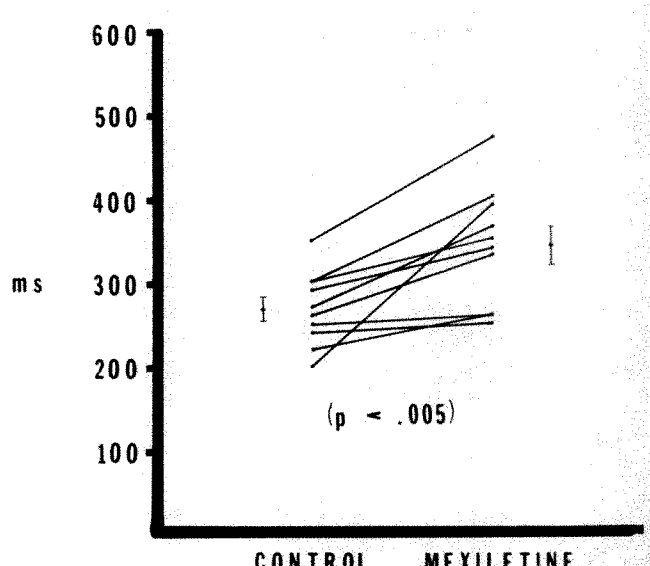

FIGURE 3. Effect of mexiletine on induced VT cycle length in 10 patients with an unsuccessful response to mexiletine. Tachycardia cycle lengths are plotted during control and mexiletine studies in individual patients. Each patient is represented by **solid circles connected by a straight line.** Group mean values are shown on the left for control and on the right for mexiletine tachycardia cycle length.

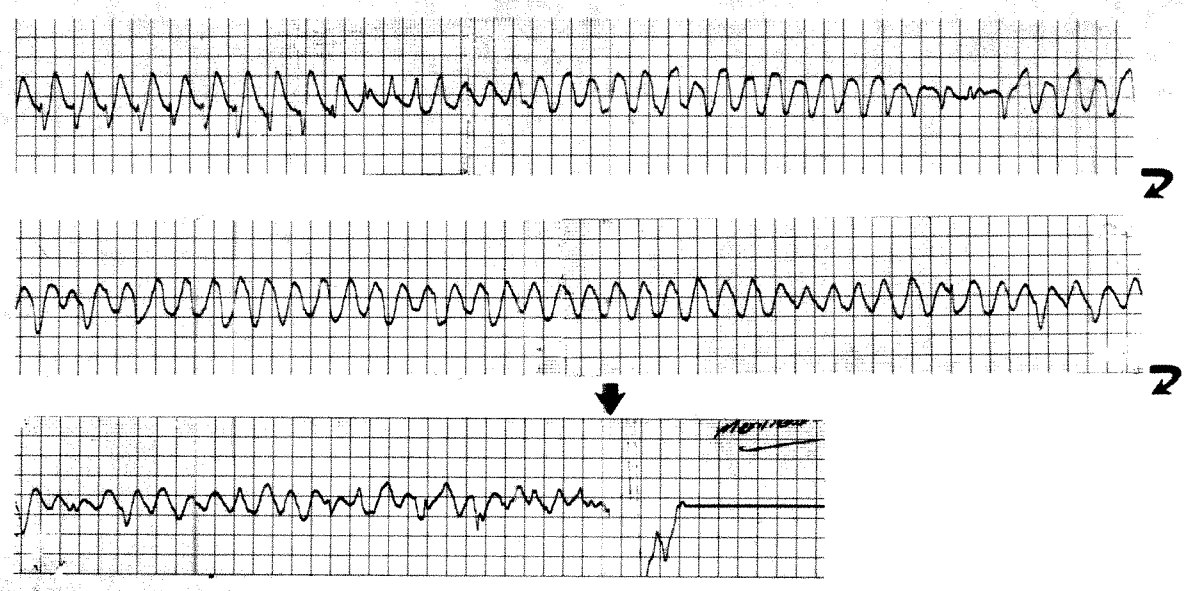

FIGURE 4. Spontaneous ventricular dysrhythmia during mexiletine therapy. Continuous electrocardiographic monitor strip of 1 of several episodes showing initial monomorphic VT converting to polymorphic VT (torsade de pointes) and deteriorating to ventricular fibrillation terminated by external direct current countershock (**bold vertical arrow**). (Discontinuity of the electrocardiographic paper is an artifact owing to the inability of the strip recorder to print continuously for longer than 6 seconds. The **straight line** after cardioversion reflects the inability of the monitor to respond to electrical signals immediately after cardioversion.)

difficult and frustrating. The continuing development of new antiarrhythmic drugs reflects the deficiencies of the currently available drugs.

One of these new drugs is mexiletine, a phenethanolamine compound chemically similar to lidocaine and possessing electrophysiologic properties resembling those of lidocaine in some aspects and quinidine in others.[9,10] Clinical trials have demonstrated its effectiveness in ventricular arrhythmias associated with various forms of heart disease when administrated parenterally or orally.[11,12] More recently, reports indicate that mexiletine may be a very useful antiarrhythmic agent in patients with recurrent ventricular arrhythmias, including patients demonstrating resistance to conventional antiarrhythmic drugs.[13,14]

Ruskin et al.,[13] in a study of 35 patients with out-of-hospital cardiac arrest due to VT or fibrillation, demonstrated inducible ventricular arrhythmia in the electrophysiology laboratory. They found mexiletine an effective drug in 9 patients when used as a single agent and in 4 patients when used in combination with other drugs. The same investigators,[14] in a study of 41 patients with recurrent ventricular arrhythmias resistant to conventional drugs, identified 17 patients in whom mexiletine suppressed ventricular arrhythmia during an acute drug trial utilizing electrophysiologic testing.

In the present study, we evaluated 17 patients with recurrent sustained VT who had inducible sustained VT during control electrophysiologic study and were found refractory to conventional antiarrhythmic drugs. We found that mexiletine failed to prevent the induction of sustained VT by programmed ventricular stimulation in 10 of 11 patients. Previous studies[3,4] have shown that this acute drug trial failure predicts the failure of long-term antiarrhythmic drug therapy in providing prophylaxis against recurrence of VT. In 5 of 17 patients, spontaneous recurrence and worsening of VT during mexiletine therapy indicated drug failure and obviated further electrophysiologic evaluation of mexiletine. In 1 patient intolerable neurologic side effects at very low doses precluded mexiletine administration, while in 7 other patients noncardiovascular adverse effects were also noted.

Of 4 patients who received long-term oral mexiletine therapy, 3 had recurrence of VT (including 1 patient who had a successful response to mexiletine during serial electrophysiologic study) within a short period (1 to 16 weeks), while 1 patient has remained free of recurrence in 6 months of follow-up.

Comparison with previous serial electrophysiologic studies: The difference in results in the present study and the 2 previous studies from Ruskin's laboratory cannot be explained by differences in pacing technique or the amount of mexiletine used, since these were similar. The explanation may be related to a difference in the selection of study patients. Patients without inducible ventricular arrhythmia or patients with only nonsustained VT during the control electrophysiologic study were not included in our study. In the study of Di Marco et al.,[14] only 22 of 41 patients had inducible sustained VT during initial electrophysiologic study. Of these 22 patients, mexiletine was effective in 4 as a single agent, and in 2 as part of a combination regimen. This represents a total response rate of 27%, and an 18% response rate when mexiletine was used as a single agent. While these rates are lower than the reported success rate of 42% when all 41 patients with various ventricular arrhythmias are considered, they are still somewhat higher than the success rate of 9% (1 of

17) in our study. Further comparison of the study population regarding the extent and severity of the heart disease, which may have some influence on drug responsiveness, is not possible since these data were not reported in their study.

In the study of Ruskin et al.,[13] only 11 of 31 patients had inducible sustained VT and 2 of 31 had inducible ventricular fibrillation during the initial electrophysiologic study. Further comparison with the present series is not possible, since the necessary data were not reported in detail. Other possible sources of differences could be the varying end points considered as successful response in the different studies and the use of mexiletine in combination with other drugs. We did not use mexiletine as part of combination regimen in the present study. Di Marco et al.[14] also made the observation that mexiletine seemed more effective in suppressing rapid (cycle length less than 325 ms) rather than slower inducible arrhythmias. We did not observe this in the present study.

Adverse effects: We observed significant neurologic or gastrointestinal side effects, most requiring dose reduction or discontinuation in 8 of 17 patients (47%). This incidence of side effects is similar to recently reported findings.[12,14–16] However, the occurrence of serious and life-threatening arrhythmia potentiation in 5 of 17 patients (29%) represents an unexpectedly high incidence of this adverse effect. This frequency is higher than that reported by Heger et al.[15] (2 of 15, or 13%) or Di Marco et al.[14] (5 of 41, or 12%).

Clinical implications: Our observations indicate that oral mexiletine is ineffective in the therapy of patients with drug-refractory, recurrent sustained VT as defined by serial electrophysiologic studies and limited clinical follow-up. In addition, its use is associated with a high incidence of adverse effects, which in a significant proportion of patients can be serious and life-threatening. Therefore, oral mexiletine does not appear useful in the therapy of drug-refractory, paroxysmal sustained ventricular VT and, if used, it should be with caution and with an awareness of its potential for serious arrhythmia potentiation.

Prolongation of the Human Cardiac Monophasic Action Potential by Sotalol

DEBRA S. ECHT, MD, LARRY E. BERTE, MD, WILLIAM T. CLUSIN, MD, PhD, ROLF G. SAMUELSSON, MD, PhD, DONALD C. HARRISON, MD, and JAY W. MASON, MD

Sotalol and propranolol are nonselective beta-adrenergic blocking agents. Sotalol at low concentration, unlike propranolol, prolongs the duration of the transmembrane action potential. In a double-blind study, the electrophysiologic effects of intravenous sotalol (0.30 or 0.60 mg/kg; n = 9) were compared with intravenous propranolol (0.15 or 0.20 mg/kg; n = 8) in 17 patients with use of bipolar suction electrodes in the right atrium and right ventricle to determine whether sotalol prolongs the monophasic action potential duration in man. After administration of sotalol, there were significant increases (paired *t* test) in the Q-T interval ($p < 0.001$), right atrial effective refractory period ($p < 0.05$), right ventricular effective refractory period ($p < 0.005$), right atrial monophasic action potential duration at 90% repolarization ($p < 0.01$), and right ventricular monophasic action potential duration at 90% repolarization ($p < 0.005$). Prolongation of the monophasic action potential duration was dependent on plasma sotalol concentration. There were no significant changes in these variables after propranolol. The spontaneous cycle length and Wenckebach cycle length increased significantly in both groups, and the mean blood pressure decreased in both, although not significantly after propranolol.

In summary, sotalol but not propranolol prolonged atrial and ventricular effective refractory periods and lengthened the monophasic action potential and the Q-T interval of human myocardium after intravenous infusion. The ability to acutely prolong repolarization at therapeutic plasma concentration is unique among known competitive beta-adrenergic receptor antagonists.

Sotalol is a nonselective beta-adrenergic receptor antagonist without intrinsic sympathomimetic or membrane-stabilizing activity. It has one third the beta-blocking potency of propranolol.[1] Earlier in vitro investigation of canine, feline, and rabbit preparations demonstrated prolongation of transmembrane action potentials in atrial and ventricular tissue during sotalol superfusion.[2,3] Monophasic action potentials can be measured in man utilizing a suction electrode catheter.[4] Duration of the monophasic action potential correlates well with the duration of the cellular action potential obtained with microelectrodes. Recently, Edvardsson[5] reported that intravenous sotalol significantly increased the right ventricular effective refractory period and monophasic action potential duration in 8 patients with chronic atrial fibrillation.

The purpose of this study was to explore the effects of sotalol on the electrophysiologic function of the heart in catheterized patients, to determine the degree of change in those effects with differing doses of sotalol, and to compare the changes with those produced by equipotent beta-blocking doses of propranolol.

Methods

Study subjects: Patients undergoing routine cardiac catheterization for clinical indications consented to electrophysiologic testing after angiography. Patients with New York Heart Association[6] functional class IV congestive heart failure, other contraindications to beta-blocking agents, major conduction disturbance in the electrocardiogram, or relative contraindication to withdrawal of ongoing beta-blocking therapy were excluded from participation in this study. antiarrhythmic agents except digoxin were discontinued at least 24 hours before the study. Patients were studied in the postabsorptive state and were unsedated except for premedication with diazepam, 10 mg orally. The patients were assigned by double-blind randomization to receive sotalol hydrochloride (MJ 1999, Mead Johnson Pharmaceutical, Evansville, Indiana), 0.30 or 0.60 mg/kg body weight, or propranolol hydrochloride, 0.15 or 0.20 mg/kg, delivered intravenously over 15 minutes by way of a constant infusion pump. The propranolol dose was increased after the study had begun, based on further data regarding relative beta-blocking potency of the 2 drugs. The sotalol dose was reduced to 0.30 mg/kg after the 10th study patient.

Electrophysiologic study: Quadripolar pacing catheters were positioned in the high right atrial region and the right ventricular apex. As described in detail by Olsson et al.[7] and Samuelsson and Sjöstrand,[8] a saline-filled suction electrode catheter (MAP Catheter, Kifa AB, Sweden) was advanced into the right atrial or ventricular cavity until the tip made contact with the endocardium. A 3-way stopcock allowed selection of either infusion of saline solution or negative pressure of 200 to 300 mm Hg from a wall suction. Application of suction enabled bipolar recording of amplified direct current signals from the central and peripheral catheter electrode terminals. Surface electrocardiographic leads I, aVF, and V_1 were recorded simultaneously with the right atrial and right ventricular electrograms and monophasic action potential tracing. An indwelling right femoral arterial catheter provided continuous systemic pressure monitoring.

Stimulation testing was performed with 2 ms square wave pulses of amplitude twice diastolic capture threshold by means of a programmable stimulator (W.P. Instruments, New Haven, Connecticut). Mean arterial blood pressure, basic intervals, Wenckebach cycle length, right atrial and right ventricular effective refractory periods, and right atrial and right ventricular monophasic action potential durations were determined in both spontaneous and constant-paced rhythms before and after infusion of either sotalol or propranolol. The same pacing cycle length was used before and after administration. The QRS and Q-T intervals were measured from the limb leads during atrial-paced rhythm and expressed as the average of 5 consecutive cycles. The Wenckebach cycle length was determined during constant atrial pacing by decreasing the cycle length 10 ms every 10 seconds, and defined as the longest atrial cycle length resulting in atrioventricular nodal Wenckebach periodicity. The right atrial and right ventricular effective refractory periods were determined in constant atrial and ventricular paced rhythms, respectively, with premature extrastimuli introduced after every 8 paced basic drive beats. The longest coupling interval of the premature extrastimulus not resulting in atrial or ventricular depolarization was the effective refractory period of that chamber. Measurements of right atrial and right ventricular action potential durations were averaged over 3 consecutive beats and determined at 50, 90, and 100% repolarization. Samples for plasma drug levels were collected from the arterial catheter before drug infusion (time 0) and at 15, 30, and 45 minutes. Drug concentrations were determined with high performance liquid chromatography.

Statistical methods: The changes in spontaneous heart rate, Q-T interval, Wenckebach cycle length, right atrial and right ventricular effective refractory periods, and right atrial and right ventricular monophasic action potential durations at 90% repolarization in constant paced rhythm were compared before and after drug administration using a two-tailed paired *t* test. Changes in right atrial and right ventricular monophasic action potential durations at 90% repolarization and right atrial and right ventricular effective refractory periods determined at different drug doses were compared with two-tailed mean *t* tests. Plasma drug levels were attained and changes in monophasic action potential durations and effective refractory periods were analyzed using Spearman's rank correlation coefficient and Fisher's method for combining independent probabilities. When appropriate, standard deviations are provided.

Results

Seventeen men were studied. Nine received sotalol and 8 received propranolol. The mean age was 53 ± 13 years in the sotalol group and 54 ± 10 years in the propranolol group. The indication for cardiac catheterization was coronary heart disease in 8 patients in the sotalol group and 6 in the propranolol group. One patient had atrial arrhythmia in the sotalol group, and 1 patient each had mitral valve prolapse and atrial septal defect in the propranolol group. The New York Heart Association functional class for symptions of congestive heart failure was determined to be class I in 8 sotalol and 6 propranolol patients, class II in 2 propranolol patients, and class III in 1 sotalol patient. Four patients received sotalol, 0.30 mg/kg, and 5 received 0.60 mg/kg. Two patients received propranolol, 0.15 mg/kg, and 8 received 0.20 mg/kg.

Electrophysiologic findings: The basic rhythm was sinus in all 17 patients except 1 with atrial fibrillation in the sotalol group in whom data requiring right atrial pacing could not be obtained. In all patients in both sotalol and propranolol groups the spontaneous cycle length and Wenckebach cycle length increased after drug infusion (Table I). Mean arterial pressure decreased from 101 to 89 mm Hg ($p < 0.005$) in the sotalol group and from 102 to 97 mm Hg in the propranolol group (difference not significant [NS]). The Q-T interval ($p < 0.001$), right atrial effective refractory period ($p < 0.05$), right ventricular effective refractory period ($p < 0.05$), right atrial monophasic action potential at 90% repolarization ($p < 0.01$), and right ventricular monophasic action potential at 90% repolarization ($p < 0.005$) increased in all patients receiving sotalol, but did not increase in any patient receiving propranolol. Right atrial and right ventricular monophasic action potential durations at 50 and 100% repolarization were prolonged to the same extent as at 90% repolarization after sotalol.

An example of prolongation of the right ventricular monophasic action potential by sotalol is shown in Figure 1. Figure 2, recorded from a patient who received propranolol, demonstrates no change in right atrial monophasic action potential duration at 90% repolarization. The mean increases in right atrial and right ventricular monophasic action potentials and right atrial and right ventricular effective refractory periods were slightly, but not significantly, greater in patients receiving 0.60 mg/kg than in those receiving 0.30 mg/kg of sotalol. There were no changes in these variables after administration of either dose of propranolol.

Drug levels: The mean peak plasma sotalol level obtained at the end of drug infusion was 2.61 ± 0.67

TABLE I Drug-Related Changes in Electrophysiologic Variables

	Sotalol							Propranolol						
	Mean Before	Mean After	Change ± SD	Increased (n)	Decreased (n)	Unchanged (n)	p	Mean Before	Mean After	Change ± SD	Increased (n)	Decreased (n)	Unchanged (n)	p

* Two-tailed paired *t* tests were utilized. Number increased or decreased refers to the number of patients in whom the variable changed by 10 ms or more. Number unchanged refers to the number of patients in whom the variable changed by less than 10 ms. Q-T intervals were measured during constant paced rhythm. BCL = basic cycle length; RA-ERP = right atrial effective refractory period; MBP = mean blood pressure; RA-MAPD 90% = monophasic action potential duration measured at 90% repolarization from the right atrial endocardium; RV-ERP = right ventricular effective refractory period; RV-MAPD 90% = monophasic action potential duration measured at 90% repolarization from the right ventricular endocardium; WCL = Wenckebach cycle length.

FIGURE 1. Right ventricular monophasic action potential duration (RV-MAPD) at 90% repolarization before and after administration of sotalol, 0.60 mg/kg, during right ventricular paced rhythm.

FIGURE 2. Right atrial monophasic action potential duration (RA-MAP) at 90% repolarization before and after propranolol, 0.20 mg/kg, during right atrial paced rhythm.

μg/ml in patients receiving doses of 0.60 mg/kg and 1.58 ± 0.33 μg/ml in those receiving 0.30 mg/kg. At the conclusion of propranolol infusions the mean peak plasma level was 370 ± 160 ng/ml after doses of 0.20 mg/kg and 200 ± 80 ng/ml after 0.15 mg/kg. There was no statistical correlation between the changes in effective refractory periods or monophasic action potential durations and peak plasma sotalol levels. Sotalol plasma levels obtained 15 minutes after infusion (when most electrophysiologic measurements were recorded) were correlated with the extent of prolongation of the monophasic action potential duration ($p < 0.05$, 2-tailed) with use of the combined probabilities of the right atrial and right ventricular monophasic action potential durations calculated by Fisher's method.

Discussion

Sotalol versus propranolol: This study demonstrates that intravenous sotalol in man prolongs the monophasic action potential durations and effective refractory periods of both atrial and ventricular myocardium whereas intravenous propranolol, in equipotent beta-blocking doses,[1,9] does not. Although the monophasic action potential duration is obtained from only a small volume of myocardial tissue, the increase in effective refractory periods and Q-T intervals suggest a generalized effect. The increase in monophasic action potential duration provides evidence for a class III cellular effect of sotalol, which has not been reported for other beta-blocking agents after intravenous administration. Contrary to the previous prediction, based on microelectrode studies, that large concentrations of sotalol would be necessary for action potential prolongation,[10] these effects are present with clinically used dosages. With intravenous administration, the prolongation in monophasic action potential duration was not significantly related to either sotalol dose or peak plasma level. However, monophasic action potential tracings were recorded approximately 15 minutes after the peak plasma levels were attained, at which time the prolongation of the monophasic action potential duration was directly correlated with plasma concentration.

Comparison with previous studies: Our findings are in agreement with those of previous animal investigations. Prolongation of the transmembrane action potential by sotalol has been described in canine Purkinje tissue and ventricular muscle, rabbit atrial tissue, and cat papillary muscle.[2,3] In vitro animal studies with propranolol by Davis et al.[11] showed a decrease in transmembrane action potential duration and effective refractory period in canine Purkinje fibers, but only at large concentrations (3 μg/ml and greater). This shortening effect was recently demonstrated in human subjects with use of the suction electrode technique.[12] In our study, the mean peak plasma propranolol level obtained for doses of 2 mg/kg was 0.37 μg/ml, and fell to less than 0.10 μg/ml during electrophysiologic measurements. Therefore, our findings of no change in monophasic action potential duration after propranolol are consistent with previous experimental results.[11,12] Recent human studies with sotalol have been contradictory. Ward et al.[13] found an increase in the atrial effective refractory period but not in the ventricular effective refractory period. Edvardsson[5] found an increase in both the right ventricular effective refractory period and right ventricular monophasic action potential duration after sotalol, but did not measure the atrial effective refractory period. He found that the sinus nodal recovery times and atrio-His bundle conduction times were prolonged after intravenous sotalol, as occurs after propranolol.

Methodology: The monophasic action potential determined with suction electrode is not a true representation of the transmembrane action potential, but rather a reflection of injury effects. However, Shabetai et al.[4] compared monophasic action potential recordings in man with transmembrane action potential recordings in animals, and found the potentials to have the same shape and duration, and similar responses to changes in heart rate, administration of calcium and digitalis, and to the introduction of premature extrasystoles. The monophasic action potential duration appears to be a quantitatively accurate index of the true action potential duration. The monophasic action potential recordings comprise a summation of a number of cells, have a lower amplitude, and cannot be equated with absolute transmembrane potential differences. Therefore, one cannot evaluate changes in action potential amplitude, resting membrane potential, or upstroke velocity using the suction electrode technique. Microelectrode studies have demonstrated no significant change in this variable after superfusion of sotalol or propranolol.[2]

Mechanism of action: Beta-adrenergic receptor antagonists inhibit the transmembrane action potential effects of catecholamines. In the absence of catecholamines, beta blockade generally does not alter the transmembrane action potential. Propranolol, but not sotalol, has been found to have weak direct membrane effects in addition to its beta-blocking properties. These class I effects include reduction in the action potential amplitude, upstroke velocity, membrane responsiveness, and conduction, and are probably due to decreased sodium influx.[10] Microelectrode studies demonstrate prolongation by sotalol of phases 2 and 3 of the action potential. Possible underlying mechanisms include augmentation of the slow inward current or a delay in onset or reduction of potassium efflux. At present there is no direct evidence to substantiate either mechanism.

There is some evidence that beta-blocking agents have different effects when administered acutely or chronically. After long-term administration of practolol in rabbits,[14] in vitro studies showed an increase in the atrial action potential duration. Long-term administration of metoprolol in human subjects was found to prolong the monophasic action potential duration, right ventricular effective refractory period, and Q-T interval.[5] Other evidence of Q-T prolongation exists for

propranolol and acebutolol.[5] It is possible that prolongation of the action potential duration is another property common to beta-blocking agents manifested acutely with sotalol, but requiring long-term therapy with other drugs.

Clinical implications: The unique combination in sotalol of class II and III actions could be beneficial in the management of arrhythmias. Amiodarone, a class III agent, has proved efficacious in the treatment of virtually all types of atrial and ventricular ectopic beats and tachyarrhythmias. Olsson et al.[15] found that long-term oral therapy with a small dose (200 mg daily) of amiodarone increased the right atrial monophasic action potential duration in 8 patients from an average of 234 to 308 ms. Although this prolongation was more pronounced than we observed with sotalol, Olsson et al. studied their patients with sinus rhythm, which was slowed by amiodarone. Intravenous and oral sotalol have been used in the treatment of atrial and ventricular arrhythmias with moderate effectiveness.[16–18] However, the studies included patients with heterogeneous arrhythmia with differing doses and routes of administration, making comparative assessment difficult. We evaluated only the intravenous effects of sotalol. Oral sotalol should be studied with cellular action potential recordings to assess whether prolongation of the action potential persists. Significant prolongation of the Q-T interval has already been reported, providing indirect evidence.

At present, clinical trials are being carried out in patients who have had a myocardial infarction to determine whether sotalol is effective in the prevention of sudden cardiac death. It is possible that the combination of beta-adrenergic receptor blockade and class III action produced by sotalol would offer greater benefit than beta blockade alone.

"Clearly filled a marked gap in the infectious disease literature"[1]
"Highly recommended"[2]
"Beautifully edited, lavishly produced"[3]

Reviewers Throughout the World are Praising Dr. Grieco's New Work.

INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Prof. Clinical Medicine, Columbia Univ. College Physicians and Surgeons, Director R.A. Cooke Institute of Allergy, St. Luke's-Roosevelt Hosp., N.Y.

Text by 47 specialists, 1,035 pages, 147 illus., 78 full-color photos. Completely indexed. $79.95.

In 36 revealing chapters are reviewed the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation. INFECTIONS IN THE ABNORMAL HOST will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy

• Index

1 "With this comprehensive work, Grieco has clearly filled a marked gap in the infectious disease literature. Various sections should be of interest to a broad range of practitioners . . . should serve as an important starting point and a useful reference source for any physician concerned with the complicated but increasingly important patient, the compromised host."
Philip A. Pizzo, MD, National Cancer Institute, **NEW ENGLAND JOURNAL OF MEDICINE**, Jan. 8, 1981

"This work will serve the physician well in caring for patients with serious infections. It is well organized and easy to use for quick reference. It also serves as an extensive review of infections in the defective host for specialists in infectious disease, pulmonary medicine, and cancer."
W. Lee Fanning, MD, **JOURNAL AMERICAN MEDICAL ASSOCIATION**, Jan. 2, 1981

"This important text should play a valuable role in the understanding and management of infections in the abnormal host and shows how clinical microbiologists, immunologists, and infectious disease clinicians can work together in the diagnosis and management of patients."
D.M. Weir, Dept. Bacteriology, Univ. of Edinburgh, **LANCET**, July 19, 1980

2 "This book is expertly edited . . . an outstanding feature is the thoroughness in which the book is indexed . . . As a comprehensive text for the academician and as a sound guide for the clinician in every field, the book is highly recommended. Immunologists, microbiologists, oncologists, internists, and specialists in infectious diseases should either purchase the book or have a copy readily available as a reference. Medical and graduate school libraries should own copies."
E.A. Gorzynski, **IMMUNOLOGICAL COMMUNICATIONS**, Sept. 7, 1980

3 "And so we must not only choose the correct antibiotic but also overcome the infection in this compromised, immunosuppressed patient or what we commonly term the person with poor resistance. This clearly calls for a book of guidance and this is it, all 1,035 pages of it, beautifully edited, lavishly produced, and with the experience and wisdom of 47 contributors."
D. Geraint James, FRCP, Dean Royal Northern Hospital, London, **MILAN DAILY MEDICAL NEWSPAPER**, May 1980

IN CHF ASSOCIATED WITH ACUTE MI

SYSTEM THAT DELIVERS

Efficacy:

- Quickly relieves pulmonary congestion with little effect on cardiac output[1]
- Helps redistribute blood flow to the infarcted myocardium[2,3]

Predictability:

- Produces dose-responsive venous and arterial dilation to help control both preload and afterload
- Tridilset,™ a special non-absorbing IV administration set, delivers Tridil with the greatest possible accuracy[4,5]

Safety:

- Metabolites have only minor activity and are rapidly excreted
- Highly concentrated Tridil (5 mg/ml) helps avoid the risk of fluid overload (especially helpful in the presence of oliguria)

***TRIDIL SYSTEM*—the preferred IV nitroglycerin in CHF associated with acute MI**

- Highest concentration currently available—easy dilution, convenient administration, conserves fluid intake.
- Non-absorbing Tridilset IV set allows precise titration
- Comprehensive clinical/technical support

TRIDIL SYSTEM

delivers a new level of therapeutic precision to the treatment of CHF associated with acute MI

Please see the following page for a brief summary of prescribing information.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinylchloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,™ an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

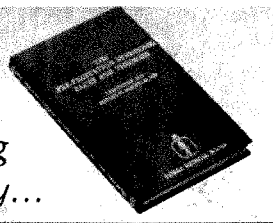
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

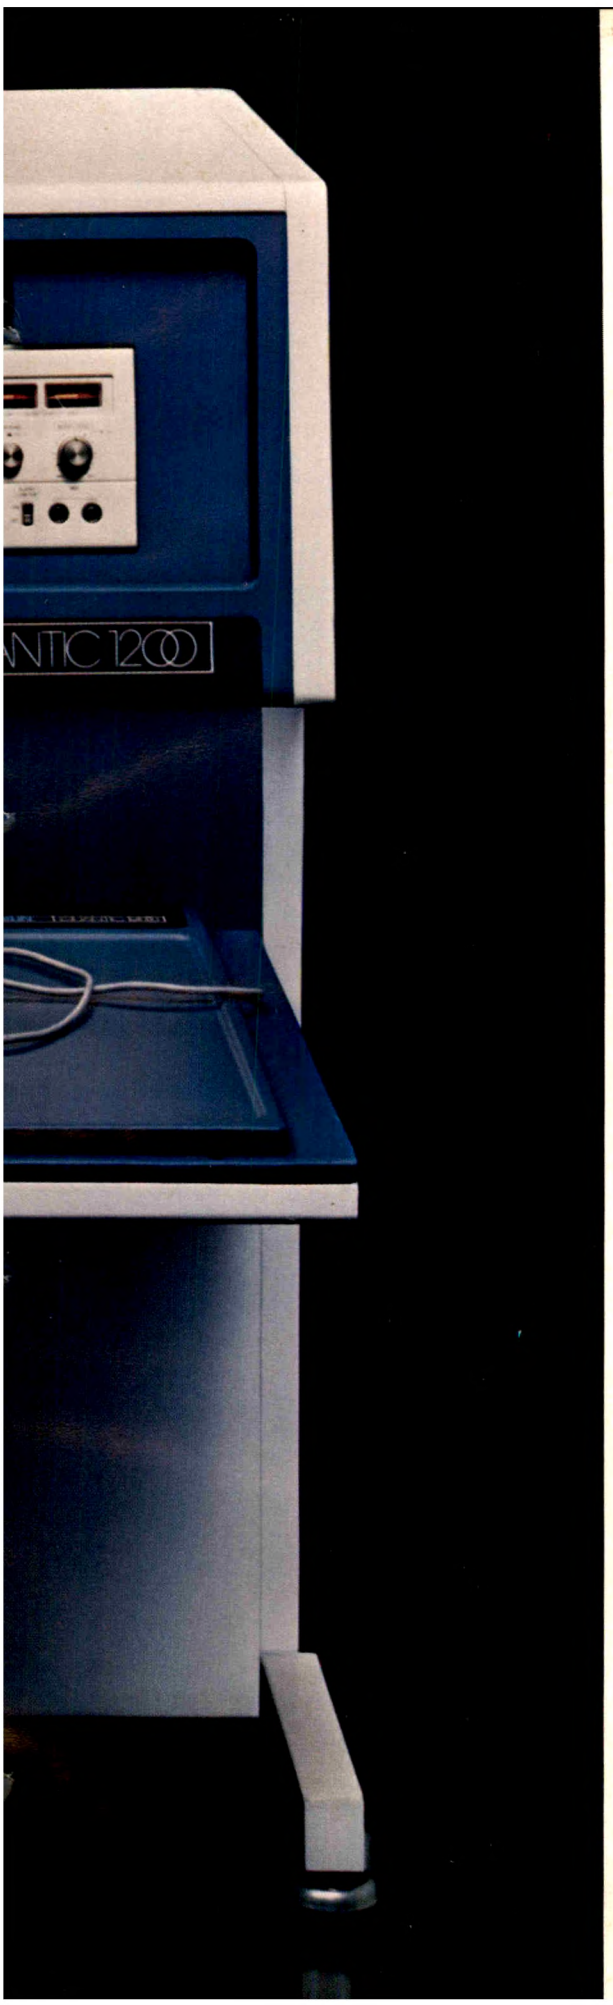
Finally.
A computer fast enough to make dynamic cardiac quantitation a practical reality.

Panasonic
PROMPT
IMAGE
FRANKLI



The Franklin Quantic 1200.

Now, for the first time, Franklin makes it possible to digitize complete cardiac cycles in real time and quantitate the massive amounts of information captured by video echocardiographic studies.

In fact, the Quantic 1200 uses all the significant information on every frame of a cycle to guide and correct the information on every other frame of the same cycle.

This allows the computer to:

- Automatically recognize and track the borders of the endocardium. (The operator has the flexibility to interrupt the process, draw new borders, and edit at any time.)
- Perform comparative analyses of normal and abnormal beats using segmental wall motion displays.
- And provide repeatable calculations on perimeters, areas, volumes, and ejection fractions.

All within a few short minutes.

So, now you can make decisions based on more complete and more precise information about the region, extent, magnitude, and timing of heart abnormalities from non-invasive images.

Furthermore, because the entire process is repeatable, relatively inexpensive, and non-invasive, the Franklin Quantic 1200 provides you with the first practical way to monitor and evaluate heart performance before and after therapy.

FRANKLIN

The Franklin Quantic 1200.

It can give you more useful information, *faster.*

It is, in fact, the first computer fast enough and powerful enough to capture and digitize the massive amounts of data present in real time ultrasound video signals.

In addition, the Quantic 1200 is the only echocardiographic computer on the market with enough power to apply the extraordinarily complex algorithms researchers are currently developing for future clinical use. These include automatic edge detection, tissue characterization, image processing, frame-to-frame averaging, motion detection, and noise reduction.

Yet, for all its sophistication, the Quantic 1200 is even simpler to operate than many home/office minicomputers.

Compare these features with any other system at any price:

SOFTWARE

Operator-friendly, screen-prompted software programs provide faster access to information and greater flexibility than any other system currently available.

Furthermore, because all programs are designed for maximum simplicity and ease of operation, no prior knowledge of computers is necessary for full clinical use of the Quantic 1200.

CLINICAL PROGRAMS

Five of the most widely accepted algorithms used to calculate 2D echocardiographic measurements of areas, volumes, ejection fractions, and other essential derived physiological data.

A full complement of M-mode programs for calculations from both video and hard copy.

Automatic Border Recognition Algorithm developed for Franklin under exclusive license by one of the nation's leading university research centers. (Clinical human validation studies ongoing.)

Full cycle analysis programs including three segmental wall motion algorithms and one area/perimeter change analysis algorithm.

REAL TIME FRAME GRABBER

Capable of capturing and digitizing complete cardiac cycles in real time.

DIGITAL STORAGE

Hard disk for efficient storage and retrieval of 1200 discreet frames of video information.

COMPUTER

Special purpose, 16 bit computer.
Half-million byte RAM memory (expandable).
High speed, high resolution graphics system.

TWO MONITORS

Two high resolution, 9-inch screens; one for prompting, one for imaging.

KEYBOARD

Typewriter quality, full alphanumeric keyboard for convenient labeling and data entry.

JOY STICK

Precision, strain gauge joy stick, custom-designed by Franklin for the specific task of tracing borders of the endocardium.

DIGITIZING PAD

High resolution, convenient digitizing pad and pen.

PRINTER

High resolution, dot matrix graphics printer.

PRINT SPOOLER

Stores and prints up to eight pages of summary. Operator never waits to perform other computer functions.

OTHER FEATURES

- Fully programmable with optional floppy disk drive and software.
- Modular software upgrades on floppy disks will be available.
- Off-line video and hard copy capability.
- On-line real time capability.
- Video archiving.
- Compatible with all video ultrasound systems.
- Portable and compact.
- Rugged, reliable, solid state components.

We make it possible.

Use of Procainamide in Patients With the Wolff-Parkinson-White Syndrome to Disclose a Short Refractory Period of the Accessory Pathway

HEIN J. J. WELLENS, MD, SIMON BRAAT, MD, PEDRO BRUGADA, MD, ANTON P. M. GORGELS, MD, and FRITS W. BÄR, MD

Like ajmaline, procainamide can be used to identify patients with the Wolff-Parkinson-White syndrome who have a short refractory period of the accessory pathway in an anterograde direction. Procainamide given intravenously in a maximal dose of 10 mg/kg body weight over a 5 minute period during sinus rhythm produced complete anterograde block in the accessory pathway in 20 of 39 patients. An electrophysiologic investigation performed 24 to 48 hours later revealed that in 19 of the 20 patients the effective refractory period of the accessory pathway was 270 ms or greater. In 18 of the 19 patients not exhibiting anterograde block in the accessory pathway, the refractory period was less than 270 ms. When ajmaline was compared with procainamide in the same patient, 100 mg of procainamide had approximately the same effect as 10 mg of ajmaline. The use of intravenous procainamide is a reliable and rapid method of identifying patients with the Wolff-Parkinson-White syndrome who may be at risk for circulatory insufficiency or sudden death in case of atrial fibrillation.

In patients with the Wolff-Parkinson-White syndrome a correlation exists between the duration of the refractory period of the accessory pathway in an anterograde direction and the shortest R-R interval between preexcited QRS complexes during atrial fibrillation.[1–3] Deterioration of atrial fibrillation into ventricular fibrillation has been reported in patients with short refractory periods of their accessory pathway in an anterograde direction.[4] We previously reported on the use of ajmaline to identify patients with the Wolff-Parkinson-White syndrome having an anterograde refractory period of the accessory pathway of 270 ms or less.[5] Because ajmaline is not available in the United States we became interested in studying the potential value of intravenous procainamide to obtain the same information.

Methods

Patients: Thirty-nine patients with electrocardiographic characteristics of the Wolff-Parkinson-White syndrome were studied. Their ages ranged from 7 to 65 years; 27 patients were male and 12 female. Twenty-seven patients had electrocardiographic documentation of a regular supraventricular tachycardia. In 7 patients atrial fibrillation had been recorded. In 3 patients electrocardiograms showing both atrial fibrillation and a regular supraventricular tachycardia were available. Two patients had no symptoms. During programmed stimulation of the heart the accessory atrioventricular pathway was located between the left atrium and the left ventricle in 19 patients, between the right atrium and the right ventricle in 8 patients, and in the septum in 12.

Protocol: The following protocol was used in all patients:

1. An echocardiogram was made to exclude the presence of idiopathic hypertropic subaortic stenosis.[6]
2. All medication was withheld for at least 4 days.
3. (a) Twenty-four to 48 hours before a programmed stimulation study and after a 12 lead electrocardiogram revealed sinus rhythm with the Wolff-Parkinson-White pattern, a maximal dose of 50 mg of ajmaline was given intravenously over a 3 minute period. Six electrocardiographic leads (I, II, III, V_1, V_5, and V_6) were simultaneously and continuously recorded during the registration. If no block in the accessory atrioventricular pathway occurred the recording was stopped 15 minutes after the end of the injection. (b) Six hours after administration of ajmaline, procainamide was given intravenously during sinus rhythm in a maximal dose of 10 mg/kg body weight over a 5 minute period. During the injection the same electrocardiographic leads were continuously and simultaneously recorded as during the injection of ajmaline. If no block in the accessory atrioventricular pathway occurred, the recording was stopped 20 minutes after the end of the procainamide injection.
4. Twenty-four to 48 hours later after informed consent was obtained, a programmed electrical stimulation study was performed[7] and the duration of the anterograde refractory period of the accessory pathway was measured using the single test stimulus technique during atrial pacing. At least 3 different basic cycle lengths were used. The effective anterograde refractory period of the accessory pathway was defined as the shortest atrial premature stimulus interval showing atrioventricular conduction over the accessory pathway from the

atrial stimulation site closest to the atrial end of the accessory pathway. In all patients in whom administration of ajmaline, procainamide, or both resulted in anterograde block in the accessory pathway, the respective dosages of ajmaline and procainamide were compared.

Results

Relation between effects of ajmaline and procainamide and duration of the effective refractory period of the accessory pathway: In 20 patients anterograde conduction over the accessory pathway could be blocked by administration of both ajmaline and procainamide. Data on the doses required and the duration of the effective refractory period of the accessory pathway in an anterograde direction are given in Table I. A typical example of anterograde block in the accessory pathway after procainamide administration is shown in Figure 1. All but 1 of the 20 patients who had anterograde block in the accessory pathway had a duration of the effective refractory period of the accessory pathway in the anterograde direction of 270 ms or more.

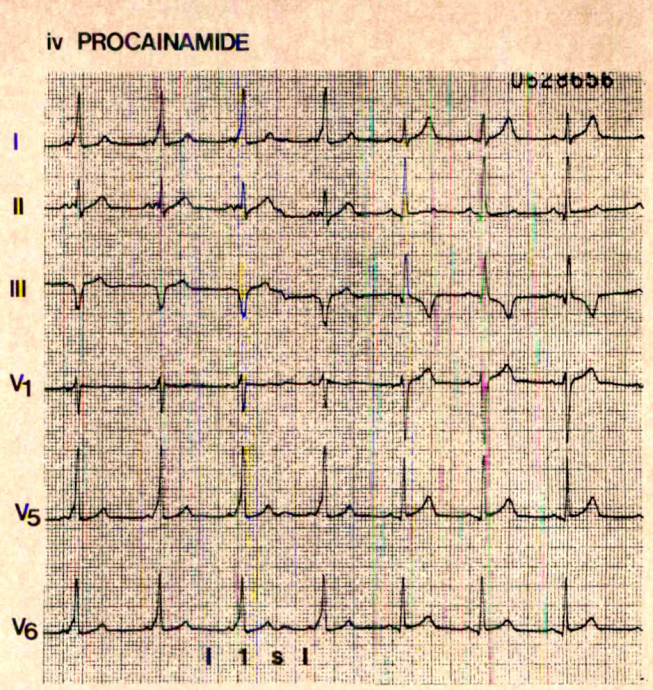

FIGURE 1. Example of the creation of complete anterograde block in the accessory pathway by injection of 300 mg of procainamide intravenously. Leads I, II, III, V_1, V_5, and V_6 were recorded simultaneously. Note the disappearance of preexcitation in the middle of the figure.

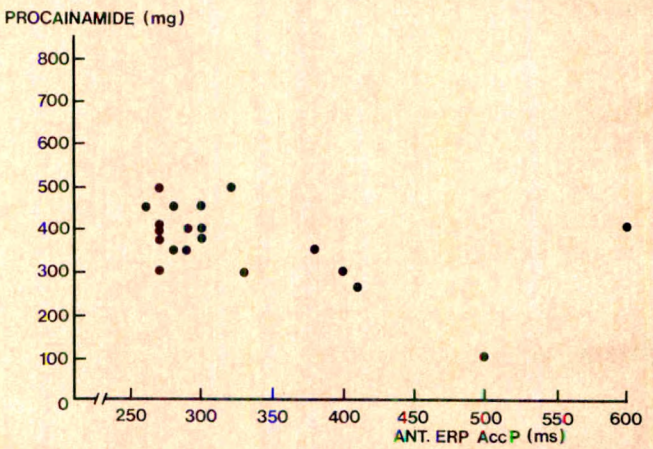

FIGURE 2. Amount of procainamide required to produce complete anterograde block in the accessory pathway (AccP) in relation to the predrug value of the anterograde (ANT.) refractory period (ERP) of the accessory pathway.

TABLE II **Relation Between Effect of Ajmaline and Procainamide on Anterograde Conduction Over the Accessory Pathway (AP)**

	Ajmaline	
Procainamide	Block AP Present	Block AP Absent
Block AP present	20	0
Block AP absent	0	19

In 18 of 19 patients not exhibiting anterograde block in the accessory pathway after administration of the drugs, the duration was 260 ms or less. Table II shows the excellent correlation between the effect of procainamide, and ajmaline and the production of complete anterograde block in the accessory pathway. Figure 2 shows that usually less procainamide was required to produce complete anterograde block in the accessory pathway the longer the predrug value of the duration of the anterograde refractory period of the accessory pathway.

Comparison of the dosages of ajmaline and procainamide required to produce anterograde block in the accessory pathway: Patients not needing the maximal dose of ajmaline (50 mg) to produce anterograde block in the accessory pathway never required the full dose of procainamide (10 mg/kg body weight) (Table I). However, in 2 patients a dose of less than the maximal dose of procainamide produced anterograde block whereas 50 mg of ajmaline was required to achieve the same result. Table I suggests that approximately 10 mg of ajmaline is equivalent to 100 mg of procainamide.

Side effects: Six patients complained of a warm feeling in the face during ajmaline injection. In 3 a visible flush developed. Three patients had dizziness during and for 3 to 10 minutes after the administration of procainamide.

Discussion

In 1964 Puech et al.[8] reported on the similar effects of procainamide and ajmaline in patients with the Wolff-Parkinson-White syndrome. This was confirmed by subsequent electrophysiologic studies.[9–12] Observation of the relation between the effects of ajmaline, quinidine, procainamide and amiodarone on the duration of the anterograde refractory period of the accessory pathway and the initial value for the duration of the anterograde refractory period of the accessory pathway[10] prompted us to compare the value of ajmaline and procainamide to identify patients with the Wolff-Parkinson-White syndrome having a short anterograde refractory period of the accessory pathway. Our results indicate that failure to produce anterograde block in the accessory pathway with procainamide given intravenously in a dose of 10 mg/kg over 5 minutes strongly suggests a short anterograde refractory period of the accessory pathway. The electrophysiologic effects of procainamide given in this way last approximately 1 hour.[9] Because of a possible hypotensive effect and the possibility of a delaying or blocking effect on subnodal conduction accompanying anterograde block in the accessory pathway, we believe that procainamide should be given under well-controlled hospital conditions.

Electrophysiologic Effects of Flecainide Acetate in Patients With Sinus Nodal Dysfunction

HARALD VIK-MO, MD, OLE-JØRGEN OHM, MD, and PER LUND-JOHANSEN, MD

Flecainide acetate (R818) is a new antiarrhythmic agent for oral and intravenous use; it has predominantly class I properties and a long plasma half-life. Electrophysiologic effects were evaluated in 11 patients with sinus nodal dysfunction before administration of flecainide acetate and 15 to 60 minutes after intravenous administration of 1.5 mg/kg body weight of flecainide acetate given over 15 minutes. In 8 of 11 patients the maximal sinus nodal recovery time increased after flecainide acetate. However, the mean maximal sinus nodal recovery time was not statistically significantly increased from 1,929 ± 184 (mean ± standard error of the mean [SEM]) to 2,770 ± 500 ms ($p < 0.10$). The corrected sinus nodal recovery time increased from 875 ± 181 before to 1,727 ± 507 ms after administration of flecainide acetate ($p < 0.05$). The sinus cycle length and sinoatrial conduction time were not significantly changed. Flecainide acetate induced a marked prolongation of the H-V interval (from 41 ± 3 to 52 ± 4 ms [$p < 0.01$]) as well as a significant increase in the A-H interval, QRS duration, and QT_{100} interval. The effective and functional refractory periods of the atria increased by 12% ($p < 0.01$) and 11% ($p < 0.01$), respectively. The atrioventricular (AV) nodal functional refractory period increased significantly by 7% ($p < 0.01$), whereas the 9% prolongation of the effective refractory period was not statistically significant. No side effects were observed. It is concluded that flecainide acetate prolongs atrial and ventricular conduction and refractoriness, and thus appears to be a potent antiarrhythmic agent. However, the sinus nodal function is depressed, and thus caution is advised in the use of flecainide acetate in patients with sinus nodal dysfunction.

Flecainide acetate (R818) is a structurally new antiarrhythmic drug with a predominantly class I mode of action, which can be given in oral and intravenous preparations.[1-4] It has a relatively long half-life in plasma of about 20 hours in patients with heart disease.[5,7] A low incidence of side effects has been reported.[5,8] Flecainide acetate has been shown to be effective against a variety of experimentally induced arrhythmias in animals.[1,9,10] In clinical studies its antiarrhythmic efficacy has been demonstrated in the management of ventricular arrhythmia,[5,6,11] Wolff-Parkinson-White syndrome, and AV nodal reentrant tachycardia.[8,12] Electrophysiologic studies in man have demonstrated a pronounced effect on infranodal and ventricular conduction, with lesser effects on the sinus node and atrium.[8,12,13]

From the Department of Clinical Physiology and the Department of Medicine, Section of Cardiology, Haukeland Sykehus, University of Bergen School of Medicine, Bergen, Norway. Manuscript received December 22, 1981; revised manuscript received May 18, 1982, accepted May 25, 1982.

Address for reprints: Harald Vik-Mo, MD, Department of Clinical Physiology, 5016 Haukeland Sykehus, University of Bergen School of Medicine, Bergen, Norway.

Patients with sinus nodal dysfunction frequently have supraventricular tachyarrhythmia.[14,15] The electrophysiologic response to antiarrhythmic drugs in these patients may differ from that in patients with normal sinus nodal function. Thus, several drugs with a class I mode of action (lidocaine, disopyramide, and mexiletine) have been reported to precipitate or exacerbate an abnormal sinoatrial function in patients with sinus nodal dysfunction[16-19]; however, this effect could not be anticipated from studies in healthy persons.

The purpose of this study was to assess the electrophysiologic effects of flecainide acetate on impulse formation, conduction, and refractoriness in patients with sinus nodal dysfunction.

Methods

Patients: The study was carried out during routine electrophysiologic evaluation in 11 patients with symptomatic chronic sinus bradycardia who had complaints of syncope, dizziness, or easy fatigability. Table I summarizes the clinical data on the patients. Informed consent was obtained from all patients. Sinus nodal dysfunction was documented by a 12 lead electrocardiogram (ECG) in all patients and by 24 hour Holter monitoring in some patients. All patients had sinus rhythm during the study with no clinical or radiologic evidence

TABLE I Clinical Data on the 11 Patients Investigated

Case	Age (yr) & Sex	Diagnosis	Major Rhythm Disturbance

of cardiac failure. Two patients (Cases 2 and 8) had the last dose of digitoxin 24 hours before the study (serum concentrations 10 and 11 ng/ml, respectively). In all other patients digitalis preparations were discontinued 2 weeks and other antiarrhythmic drugs 1 week before the study.

Electrophysiologic procedure: The patients were studied in the morning after an overnight fast. No premedication was given. Three electrodes were introduced using the percutanous Seldinger technique from a femoral vein. A quadripolar electrode was positioned in the right ventricle to record His bundle activity. Two bipolar electrodes were positioned in the right atrium, 1 for atrial pacing and the other for recording atrial activity. His bundle, right atrial, and surface electrocardiograms (leads I and III) were recorded on an Elema-Schonander Mingograph at a paper speed of 100 mm/s.

Methods: Programmed stimulation was performed using a Medtronic pulse generator model 5325 with a 1.8 ms pulse duration and output 3 times the diastolic threshold. Sinus nodal recovery time and corrected sinus nodal recovery time were studied with atrial overdrive pacing at rates of 80 to 160 beats/min,[20] and measured from the last paced atrial beat to the next spontaneous atrial or AV junctional escape beat. Maximal sinus nodal recovery time was defined as the longest atrial pause after the sudden cessation of pacing at any tested heart rate. Sinoatrial conduction time was measured by the atrial extrastimulus technique on spontaneous rhythm.[21] The refractory periods of the atrium and AV node were measured with the programmed extrastimulus technique during atrial pacing at a constant cycle length of 750 ms.[22] Refractory periods were calculated using the following terms: S is the pacing stimulus, A is the right atrial electrogram, H is the His bundle potential, and V is the earliest recorded ventricular activity taken from either surface leads or intracardiac electrograms. S_1, A_1, H_1, and V_1 were deflections from the last driving stimulus at a constant heart rate. S_2, A_2, H_2, and V_2 were deflections from the premature atrial stimulus. The effective refractory period of the atrium was defined as the longest S_1-S_2 interval at which S_2 failed to produce atrial depolarization, and the functional refractory period of the atrium as the shortest recorded A_1-A_2 interval. The effective refractory period of the AV node was defined as the longest A_1-A_2 interval at which A_2 failed to produce H_2, and the functional refractory period of the AV node as the shortest H_1-H_2 interval recorded. The A-H interval, used to define AV nodal conduction time, was measured from the initial deflection of A to the start of H deflections in the His bundle electrocardiogram. The H-V interval, representing the His-Purkinje conduction time, was measured from the start of the H deflection in the His bundle electrocardiogram to the earliest sign of ventricular activity in either recorded lead. Sinus cycle length (mean, 10 heart cycles) and QRS duration were measured during sinus rhythm. The Q-T interval was measured after 1 minute of atrial pacing at a rate of 100 beats/min (Q-T_{100} interval) from standard lead I.

Flecainide acetate administration: The studies were carried out before administration of flecainide acetate and repeated 30 minutes after the start of drug administration. Flecainide acetate was given in a dose of 1.5 mg/kg body weight as a slow intravenous injection over 15 minutes. Care was taken that the measurements were always obtained in the same order before and after drug administration. Venous blood samples for analysis of plasma concentrations of the drug were taken immediately before and 30 and 60 minutes after start of drug administration. Plasma concentrations of flecainide acetate were measured with gas-liquid chromatography.[5,23]

Statistical analysis: The patients served as their own controls. Comparisons were performed between corresponding registrations before and after drug administration using the Wilcoxon nonparametric test for paired data (two-tailed)[24]; $p < 0.05$ was regarded statistically significant.

Results

The infusion of flecainide acetate was accomplished without any extracardiac side effects. A few patients had transient dizziness during the electrophysiologic testing, but no patient had clinical symptoms related to administration of flecainide acetate. The mean arterial blood pressure was 107 ± 3 (mean ± SEM) before and 110 ± 3 mm Hg after drug administration (not statistically significant [NS], n = 11). The blood levels of flecainide acetate were 230 ± 74 and 200 ± 63 ng/ml 30 and 60 minutes after initiation of drug infusion, respectively.

Sinus nodal function: Sinus cycle length was not significantly changed by the drug (Table II). Maximal sinus nodal recovery time increased in 8 of the 11 patients. In 3 of these patients the prolongation of maximal sinus nodal recovery time was marked, ranging from 1,990 to 3,700 ms (Fig. 1). The maximal corrected sinus nodal recovery time was significantly increased by flecainide acetate ($p < 0.05$, n = 11). Before drug administration 5 patients had a prolonged sinoatrial conduction time of more than 120 ms. The sinoatrial conduction time was not significantly changed by flecainide acetate (NS, n = 8), although in the patient with the greatest prolongation, the value increased from 300 to 712 ms after drug administration. Sinoatrial conduction time could not be calculated in 2 patients because of an unstable sinus cycle length.

Intracardiac conduction: Flecainide acetate caused a prolongation of the QRS duration by 11% ($p < 0.01$, n = 11) and of the Q-T_{100} interval by 5% ($p < 0.01$, n = 11) (Table III). The A-H interval increased in 10 of 11 patients, ranging from 5 to 45 ms, and was unchanged in

A-ERP and A-FRP = effective and functional refractory periods of the atrium; AV-ERP and AV-FRP = effective and functional refractory periods of the atrioventricular node.

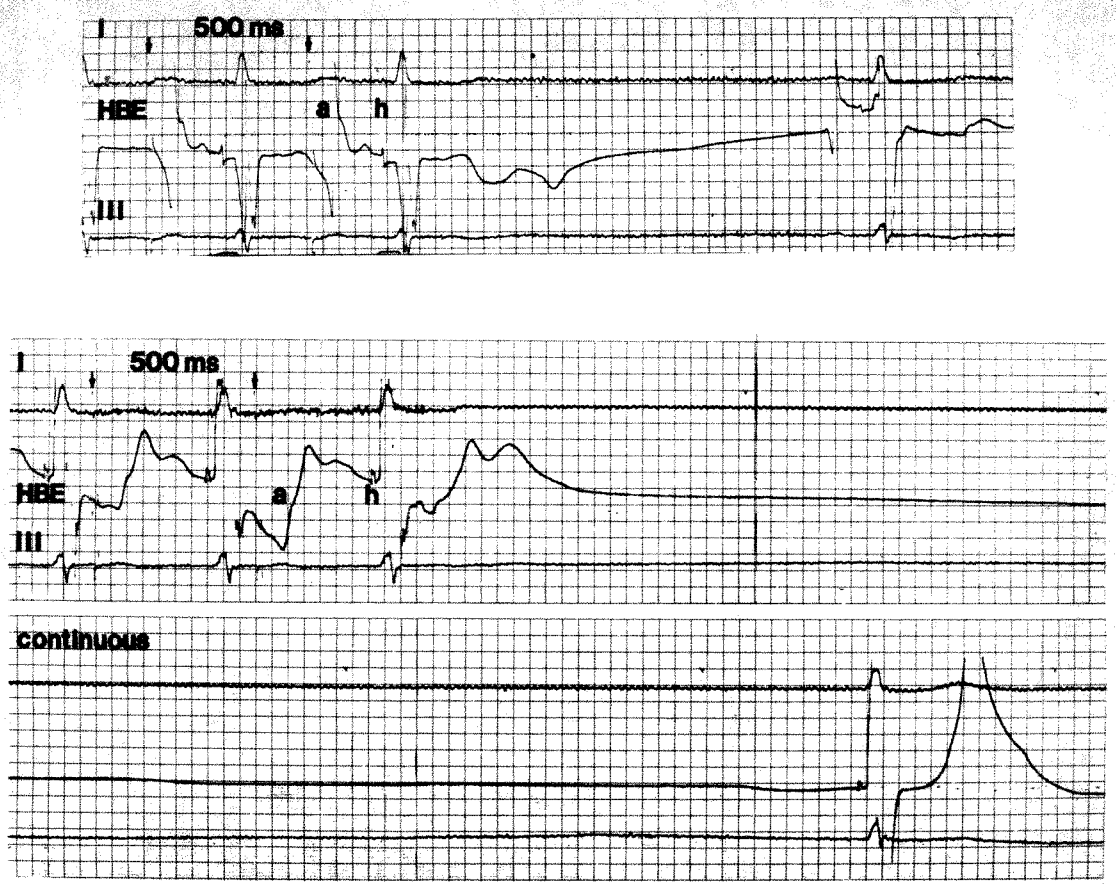

FIGURE 1. Representative electrocardiographic recordings from Patient 11. The longest sinus nodal recovery times recorded before (**upper strip**) and after flecainide acetate infusion (**lower strips, continuous**) are shown. After flecainide infusion sinus nodal recovery time was prolonged at all atrial pacing rates from 110 to 160 beats/min (2,760 to 5,270 ms). The longest pause shown occurred after an atrial pacing rate of 120 beats/min and was followed by an atrioventricular junctional escape beat. I and III = electrocardiographic standard leads I and III; a = atrial *a* wave; h = His deflection; HBE = His bundle ECG; ↓ = the 2 last pacing stimuli with a 500 ms interval.

1 patient ($p < 0.01$, n = 11). The pacing cycle length at which Wenckebach AV nodal block occurred was 140 ± 16 beats/min before and 135 ± 16 after drug administration, respectively (NS, n = 10). The H-V interval increased in 10 patients, ranging from 5 to 25 ms, and was unchanged in 1 patient ($p < 0.01$, n = 11). We did not observe H-V block in the patient with a prolonged H-V interval, left anterior hemiblock, and right bundle branch block (Case 8), or in the other patients with normal conduction.

Refractory periods: Both the effective and functional refractory periods of the atrium increased significantly after administration of flecainide, by 12% ($p < 0.01$, n = 11) and 11% ($p < 0.01$, n = 11), respectively (Table IV). The effective refractory period of the AV node could be measured in only 8 patients because the refractory period of the atrium was reached earlier in the 3 remaining patients. Flecainide acetate prolonged the AV nodal effective refractory period in 7 of the 8 patients (NS, n = 8). The A-V nodal functional refractory period increased in 9 patients and was unchanged in the other 2 ($p < 0.01$, n = 11).

Discussion

This study was designed to evaluate the electrophysiologic effects of flecainide acetate in patients with documented disturbances of sinus nodal function. The drug, 1.5 mg/kg body weight, given as a slow infusion over 15 minutes, had a mean plasma flecainide acetate level within the therapeutic range of the drug.[4,13] The drug was well tolerated and no side effects were observed.

The prolongation of sinus nodal recovery time found in our patients with sinus nodal dysfunction could not have been predicted from findings in animal experiments[1] or from studies in healthy persons,[25] in which essentially normal sinus nodal recovery time is reported after administration of flecainide acetate. However, Seipel et al.,[13] using flecainide acetate in doses of 1.0 and 2.0 mg/kg in patients with normal sinus nodal function, found a 37% prolongation of corrected sinus nodal recovery time at the larger dose, with no effect observed at the smaller dose. They suggested that a dose-related depression of the sinus nodal function by flecainide

acetate might be present. In our patients with documented sinus nodal dysfunction, a more pronounced prolongation (97%) of corrected sinus nodal recovery time was found. In 3 of 11 patients prolongation of the corrected sinus nodal recovery time was marked, ranging from 2,070 to 3,568 ms. The cause of the depressant effect of flecainide on sinus nodal function observed in this study is not known. Spontaneous variation in autonomic tone seems unlikely because basic cycle length was the same before and after drug infusion. Several drugs with class I properties are known to severely aggravate abnormal sinus nodal function, but the mechanism for this effect is not clear.[16,19] In addition to a possible direct membrane depressant effect on the sinus node caused by the drug, a more profound suppression of the sinus node during atrial overdrive pacing might occur. Drugs with a vagolytic effect have been shown to prolong sinus nodal recovery time because of facilitation of retrograde sinoatrial conduction and thereby allow more pronounced suppression of the sinus node during atrial overdrive pacing.[26] However, the sinoatrial conduction time, estimated by the extrastimulus technique used in this study, revealed no significant change after drug administration. It is therefore less likely that our observed depressant effect on sinus nodal function is due to enhancement of retrograde sinoatrial conduction during atrial pacing.

In accordance with earlier investigations, we found reduced AV nodal and intraventricular conduction times after administration of flecainide acetate.[8,13] The most profound effect was on intraventricular conduction, where we found an 11% increase in the QRS duration and a 27% increase in the H-V interval. This effect on infranodal conduction is more pronounced than in animal experiments,[1] but is similar to other studies in man.[8,24] None of our patients exhibited higher degrees of AV block. The only patient (Case 8) in this study who had an intraventricular conduction disturbance had an increase in AV and H-V intervals similiar to the other patients. However, Seipel et al.[13] described 2 patients with bundle branch block who had infranodal block after receiving a large dose of flecainide acetate (2 mg/kg) intravenously. Further clinical experience is necessary to define the importance of these findings in patients with AV conduction disturbances. However, the potency of the drug for depressing AV conduction is a beneficial property in the treatment of tachyarrhythmia. Thus, Orning[8] and Hellestrand et al.[12] found a marked slowing of conduction in accessory pathways in patients with Wolff-Parkinson-White syndrome and AV nodal reentrant tachycardia. The drug was extremely effective in the acute management of these tachyarrhythmias. The increase in atrial refractory periods in this study, together with a slowing of intraatrial conduction,[13] effected by flecainide acetate, also suggests a therapeutic potential of the drug in supraventricular tachyarrhythmia.

We found a small (5%) but significant increase in Q-T_{100} after administration of flecainide acetate. However, the observed Q-T prolongation is not as large as is usually found with other class I antiarrhythmic drugs such as quinidine[27] and can largely be explained by the QRS prolongation.

In view of our findings, we conclude that flecainide acetate prolongs intracardiac conduction and refractory periods in the atrium, AV node, and ventricle, and thus it appears to be a potentially effective antiarrhythmic drug. It did not alter spontaneous heart rate. However, the drug depresses sinus nodal function in patients with sinus nodal dysfunction and should be used with caution in such patients.

Epicardial Activation of the Human Ventricle: Effects of Left Ventricular Hypertrophy

ISAAC WIENER, MD, BRUCE MINDICH, MD, and ROBERTA PITCHON, RN

To determine the effects of left ventricular hypertrophy on epicardial activation of the human heart, intraoperative epicardial mapping of 40 to 66 points was performed in 10 patients undergoing aortic valve replacement. Mean calculated left ventricular mass was 364 ± 98 g. All patients had normal left ventricular contraction. Earliest epicardial activation occurred in the anterior right ventricle in all patients. In 9 patients, it was the only epicardial breakthrough point. One patient had a single inferior left ventricular breakthrough point. Epicardial activation spread from the right ventricle towards the left ventricle in both the anterior and inferior direction. Latest epicardial activation occurred at the base of the left ventricle in 9 patients and the base of the right ventricle in 1.

When compared with patients with coronary artery disease, normal ventricular contraction, and no left ventricular hypertrophy, patients with hypertrophy had fewer left ventricular breakthrough points ($p < 0.001$) and were more likely to have latest activation at the left ventricular base ($p < 0.001$).

We conclude that left ventricular hypertrophy is associated with marked changes in the pattern of epicardial activation. These changes may reflect delay in spread from endocardium due to the increased wall thickness.

The spread of electrical activation through the human heart has been studied both in reperfused hearts and by electrical mapping at surgery.[1–3] We recently described the changes in epicardial activation that occur in patients with coronary artery disease and regional contraction abnormalities.[4] In this report we present the results of epicardial mapping in patients with left ventricular hypertrophy.

Methods

Patients: Epicardial mapping was performed in 10 patients undergoing aortic valve replacement. The clinical and electrocardiographic features of the patients are summarized in Table I. There were 6 male and 4 female patients with a mean age of 65 ± 11 years. Seven patients had predominant aortic stenosis and 3 had predominant aortic insufficiency. An intraventricular conduction defect, acute myocardial infarction, or acute ischemic syndrome was not present in any patient, and no patient was receiving antiarrhythmic medication.

Preoperative evaluation: All patients underwent diagnostic quality echocardiography and diagnostic cardiac catheterization preoperatively. Left ventricular mass was calculated from the echocardiographic measure of septal and left ventricular posterior wall thickness according to the formula of Devereux and Reichek.[5] Regional wall motion as analyzed by ventriculography was normal in all patients.

Epicardial mapping: Patients were operated on through a median sternotomy. Mapping was performed during stable sinus rhythm, after cannulation of the great vessels but before institution of cardiopulmonary bypass. Simultaneous recordings were made of 3 body surface electrocardiogram leads, a bipolar reference ventricular electrogram, and a bipolar electrogram from the exploring probe. The reference electrode consisted of 2 stainless steel suture electrodes attached to the anterior right ventricular wall. The roving electrode consisted of 2 electrodes that were 2 mm apart and embedded in a plastic mesh.

Bipolar electrograms were recorded from 40 to 66 predetermined epicardial sites. Five to 15 right ventricular sites and 35 to 51 left ventricular sites were studied in each patient.

* Scott's criteria for left ventricular hypertrophy (LVH): RI + SIII (R wave amplitude lead I + S wave amplitude lead III) > 25 mm; R aVL >7.5 mm; R aVF >20 mm; S aVR >14 mm; SV_1 or V_2 + R V_5 or V_6 >35 mm; R V_5 or V_6 >26 mm; R + S (R + S wave amplitudes) in V lead >45 mm.

AI = aortic insufficiency; AV grad mean = mean aortic valve gradient; CAD = coronary artery disease (% stenosis); IVST = interventricular septal thickness; LAD = left anterior descending; LVM = left ventricular mass; LVID = left ventricular internal dimension; PWT = posterior wall thickness; RCA = right coronary artery.

Signals were isolated, amplified, and recorded at 200 mm/s paper speed on an Irex multichannel oscilloscopic recorder. Surface leads were recorded at 0.1 to 40 Hz and epicardial leads at 40 to 500 Hz. Heart rate and QRS morphology remained stable throughout the mapping period. Mapping was completed within 5 to 10 minutes in each patient. There was no morbidity from the mapping procedure.

Measurements were performed from the peak of the major deflection of the reference electrogram to the peak of the major deflection of the electrogram from the roving electrode. The interval from the earliest onset of the QRS in the body surface leads to the reference electrogram was added to the interval from the reference electrogram to the roving electrogram to determine local activation time. Local activation times were calculated as the mean of 5 to 10 beats in stable sinus rhythm. Measurements were considered accurate to ± 5 ms, and measurements on individual beats at a given site were always within the range.

Epicardial breakthroughs were defined as sites of emergence of a radially propagating wave front at the epicardial surface, providing an island of early activation, completely surrounded by points of later activation. Latest epicardial activation was considered the site of latest recordable ventricular activation.

Comparison with patients without hypertrophy: To delineate changes due to left ventricular hypertrophy, we compared our present findings with our previously published data from 9 patients with coronary artery disease and normal ventriculograms.[4] None of these patients had any clinical, electrocardiographic, or echocardiographic evidence of left ventricular hypertrophy nor was the left ventricle thickened at surgery. In these 9 patients, earliest epicardial breakthrough site was the anterior right ventricle, followed by 2 left ventricular breakthrough sites, 1 in the anterior left ventricle and 1 in the inferior left ventricle in each patient. The latest epicardial activation site was located at the base of the right ventricle in 7 patients and at the base of the left ventricle in 2 patients.

Results

Echocardiographic and catheterization findings: Echocardiographic and catheterization findings are summarized in Table I. Seven patients had aortic stenosis and 3 had aortic regurgitation. All patients had increased wall thickness on echocardiography with septal and posterior wall thickness of 12 to 18 mm and 12 to 15 mm, respectively. Left ventricular mass as calculated from the echocardiogram ranged from 260 to 523 g (mean 364 ± 98).

Electrophysiologic findings: Epicardial electrograms from a patient with left ventricular hypertrophy

ALV = anterior left ventricle; ARV = anterior right ventricle; EBT = early breakthrough site; ILLV = inferolateral left ventricle; IVL = inferior left ventricle; LLV = lateral left ventricle.

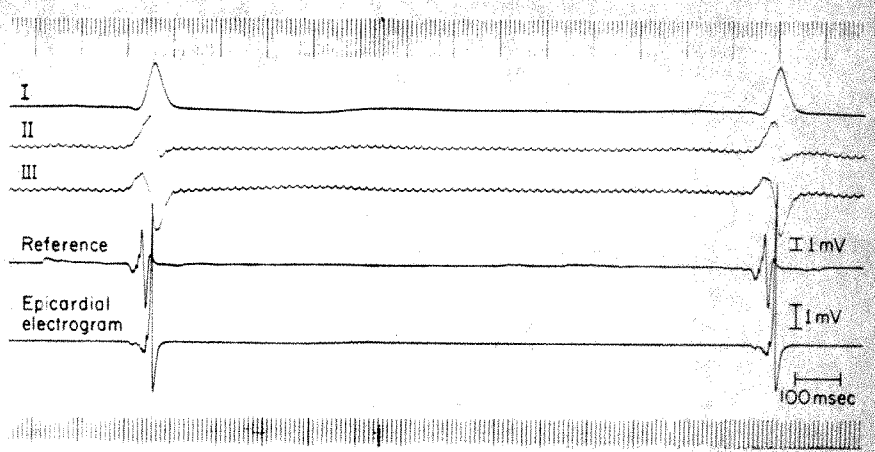

FIGURE 1. Epicardial electrogram from a patient with left ventricular hypertrophy. Three surface leads, a reference electrogram from the right ventricle, and a bipolar electrogram from the roving probe are recorded simultaneously.

are illustrated in Figure 1. A complete epicardial map of a patient with left ventricular hypertrophy is illustrated in Figure 2. Electrophysiologic data from all 10 patients are summarized in Table II.

Epicardial breakthrough: Each patient had the earliest epicardial breakthrough in the anterior paraseptal right ventricle. In 9 patients with hypertrophy this site was the only epicardial breakthrough point and there were no left ventricular breakthrough sites. One of the 10 patients with hypertrophy had a second breakthrough on the inferior surface of the left ventricle, which compares with 1 right ventricular and 2 left ventricular breakthrough sites in 9 of 9 patients without hypertrophy. When compared with patients without hypertrophy, patients with left ventricular hypertrophy had fewer left ventricular breakthrough points ($p < 0.001$).

Latest epicardial activation: Latest epicardial activation occurred at the base of the left ventricle in 9 patients and at the base of the right ventricle in 1, which compares with the base of the left ventricle as the latest activation site in 2 of 9 patients without hypertrophy ($p < 0.001$).

Spread of activation: Activation of the left ventricle occurred after activation of the right ventricle in all patients. The anterior left ventricle was activated after the anterior right ventricle, and the inferior left ventricle was activated after the inferior right ventricle.

Correlation of mapping and electrocardiographic findings: Mapping findings were not related to electrical axis, voltage, or presence of a strain pattern on electrocardiogram.

Discussion

Durrer et al.[1] defined the spread of activation through the human heart by detailed epicardial and intramural mapping of hearts extirpated from victims of automobile accidents. No patient had evidence of heart disease. The earliest endocardial activation sites were the paraseptal region at the base of the anterior papillary muscle, the central interventricular septum, and the paraseptal region at the base of the posterior papillary muscle. Activation spread in an endocardial to epicardial direction with epicardial breakthrough points on the anterior right ventricle, anterior paraseptal left ventricle, and posterior paraseptal left ventricle. Using intraoperative epicardial mapping, Wyndham et al.[3] in patients "without conduction defects" and we[4] in patients with coronary artery disease without asynergy demonstrated that epicardial breakthrough occurred in the right ventricle followed by the anterior and inferior left ventricle.

Previous studies of activation in patients with left ventricular hypertrophy, recording unipolar leads from a few epicardial sites, demonstrated generalized delays in activation with large amplitude unipolar com-

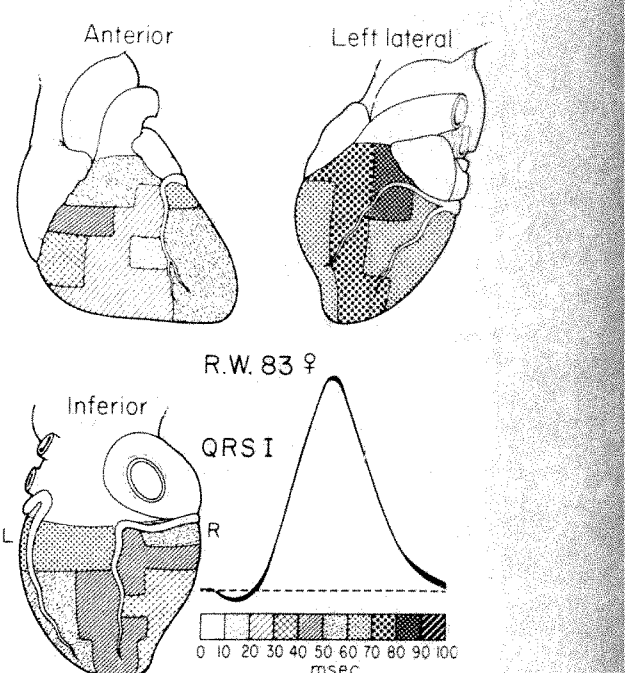

FIGURE 2. Epicardial map from a patient with left ventricular hypertrophy. Note a single epicardial breakthrough site on the anterior right ventricle. Activation spreads both anteriorly and inferiorly to the left ventricle. The latest activation site is the base of the lateral left ventricle.

plexes.[6,7] Wyndham et al.[8] described epicardial activation in a single patient with left ventricular hypertrophy, as seen at surgery. They found normal right ventricular breakthrough sites but none on the left. The left ventricle was activated by anterior and inferior spread from the right ventricle. The latest epicardial activation site was the base of the left ventricle. Animal[9,10] and human[11,12] studies have demonstrated delayed epicardial activation of the right ventricle in right ventricular hypertrophy.

Our study is the first to systematically examine the pattern of epicardial activation in patients with left ventricular hypertrophy. We found that left ventricular hypertrophy is associated with marked reduction in left ventricular epicardial breakthrough sites. Epicardial activation appears to spread anteriorly and inferiorly from the right ventricle. Latest epicardial activation generally occurs at the lateral base of the left ventricle.

These alterations may be due to delay in endocardial to epicardial conduction in hypertrophied muscle. Such delay would allow for fusion of activation from adjacent areas and elimination of discrete epicardial breakthrough. Delay of spread through the thickened left ventricle would cause the left ventricular base to be activated after the right ventricular base.

An alternative explanation for our findings is the hypothesis of Piccolo et al.[13] that electrocardiographic changes in left ventricular hypertrophy are due to coexisting disease in the bundle branch system. Wyndham et al.[14] showed that in the presence of left anterior hemiblock there are no anterior left ventricular breakthrough sites and in the presence of left bundle branch block there are no left ventricular breakthrough sites.[8] Thus, some form of bundle branch delay might explain the absence of left ventricular breakthrough points in patients with hypertrophy. We think this explanation is less likely, especially because our findings were consistent in patients with and those without left axis deviation.

We previously reported that epicardial breakthrough sites are absent in areas of akinesia and dyskinesia.[4] Thus, the changes that occur in areas of hypertrophy are similar to those seen in zones of asynergy. Our findings provide a baseline for the interpretation of abnormalities seen in patients with arrhythmia.

Influence of the Autonomic Nervous System on the Q-T Interval in Man

KEVIN F. BROWNE, MD, DOUGLAS P. ZIPES, MD, JAMES J. HEGER, MD, and ERIC N. PRYSTOWSKY, MD

Drugs that affect the autonomic nervous system can influence the Q-T interval directly or by changing the heart rate. Bazett's formula to correct for rate may be misleading after certain drug interventions. This hypothesis was tested in 20 patients receiving both propranolol (0.15 mg/kg intravenously) and atropine (0.03 mg/kg intravenously). Six patients received propranolol first, 7 patients received atropine first, and 7 patients received atropine plus propranolol simultaneously. During control and after drug intervention, the Q-T interval was measured directly in sinus rhythm and during a fixed atrial paced rate, and was calculated using Bazett's formula. The ventricular effective refractory period was also determined in 6 patients after administration of atropine plus propranolol. The sinus cycle length (836 ± 156 to 648 ± 84 ms, mean ± standard deviation), measured Q-T interval (367 ± 26 to 329 ± 26 ms), and atrially paced Q-T interval (330 ± 28 to 315 ± 27 ms) shortened after atropine plus propranolol ($p < 0.001$), but the corrected Q-T interval with use of Bazett's formula did not change (402 ± 33 to 412 ± 24 ms). The ventricular effective refractory period also shortened from 241 to 20 to 218 ± 21 ms after atropine plus propranolol ($p < 0.02$). The sinus cycle length increased after propranolol (750 ± 97 to 907 ± 108 ms, $p < 0.001$), but no change occurred in the measured Q-T interval or atrial paced Q-T interval although the corrected Q-T interval using Bazett's formula was greatly shortened (428 ± 15 to 391 ± 22 ms, $p < 0.001$). The sinus cycle length, measured Q-T interval, and atrially paced Q-T interval decreased after atropine ($p < 0.01$), but the corrected Q-T interval lengthened (375 ± 29 to 418 ± 28 ms, $p < 0.01$).

***In summary*, atropine and atropine plus propranolol shorten the Q-T interval independent of rate, demonstrating a direct vagal effect on the Q-T interval. Bazett's formula inaccurately predicts the Q-T interval after administration of atropine, propranolol, and atropine plus propranolol.**

The Q-T interval is an approximate measure of myocardial depolarization and repolarization and, like ventricular refractoriness,[1] is influenced by changes in heart rate.[2,3] Measures to correct for heart rate have included formulas derived by Bazett[3] and others.[4,5] However, drugs that alter both heart rate and ventricular refractoriness might have a complex effect on the Q-T interval. Formulas to correct for heart rate during application of these drugs may yield erroneous results for the Q-T interval. For example, although propranolol appears to shorten the Q-T interval after the changes in heart rate that it produces are corrected by Bazett's formula,[6,7] recent data[8,9] suggest that when the rate is held constant by atrial pacing during administration of propranolol, the Q-T interval does not shorten.

Recently, we[10] demonstrated that atropine or atropine and propranolol shortened the ventricular effective refractory period in man, measured with programmed stimulation of the right ventricle. However, the effects of atropine and the combination of atropine and propranolol on the Q-T interval have not been reported. The purpose of this study was threefold: (1) to determine the effects of atropine, propranolol, and atropine plus propranolol on the Q-T interval during fixed-rate atrial pacing; (2) to compare these Q-T measurements with those corrected for rate using Bazett's formula[3]; and (3) to correlate these findings with measurement of ventricular refractoriness determined with programmed ventricular stimulation.

Methods

Study patients: Twenty patients undergoing electrophysiologic study were selected prospectively for autonomic manipulation (Table I). Requirements for selection were that the patient (1) had no contraindication to intravenous administration of propranolol (0.15 mg/kg body weight) and

TABLE I Patient Characteristics

Case	Age (yr) & Sex	Heart Disease	Diagnosis
1	31M	None	Repetitive monomorphic VT[21]
2	62M	CAD	VT
3	22F	MVP	VT
4	53F	None	VT
5	61M	CAD	VT
6	50M	None	Syncope
7	56M	None	Sinus bradycardia
8	33M	None	Episodic Mobitz type I AV block
9	15M	None	Episodic Mobitz type I AV block
10	32M	None	Sinus bradycardia
11	61F	None	VT
12	30M	None	Paroxysmal SVT
13	21F	None	Sick sinus syndrome
14	27F	None	Frequent PVC, palpitation
15	39M	None	Sick sinus syndrome
16	33F	None	VT
17	57F	CAD	VT
18	29F	MVP	VT
19	40M	MVP	VT
20	19F	None	VT

AV = atrioventricular; CAD = coronary artery disease; MVP = mitral valve prolapse; PVC = premature ventricular complexes; SVT = supraventricular tachycardia; VT = ventricular tachycardia.

atropine (0.03 mg/kg), (2) had ventricular complexes with a QRS duration of 100 ms or less, (3) had clearly discernible T waves, and (4) gave written informed consent for the study. Patients whose U wave merged with the T wave were excluded.

All patients underwent complete electrophysiologic study, details of which may be found elsewhere.[10,11] In all patients the Q-T interval was measured in complexes generated during atrial pacing at the high right atrium. Ventricular refractoriness was determined during pacing at the right ventricular apex using the same pacing cycle length before and after drug administration. Electrocardiographic leads I, II, III, and V_1 were recorded simultaneously throughout the study.

Q-T measurement: For each patient, the lead in which the Q-T interval was seen best was used before and during drug interactions. The Q-T interval was measured from the onset of the Q (or R) wave to the termination of the T wave, which was determined by the intersection of a tangent drawn to the steepest slope of the downsloping portion of the T wave and the isoelectric baseline.[2] During atrial pacing, 1:1 atrioventricular conduction was maintained and each cycle length was recorded for 8 or more complexes. The Q-T interval was measured in the last paced complex at the same paced rate and in the same lead before and during drug interventions. All measurements were done at a paper speed of 50 mm/s. The Q-T interval and ventricular refractory period measurements were done by separate investigators who were blinded to each others' data.

Autonomic blockade: For each patient atropine and propranolol were administered only after completing the control part of the electrophysiologic study, including programmed atrial and ventricular stimulation. Propranolol, 0.15 mg/kg, was given intravenously at 1 mg/min. Atropine, 0.03 mg/kg, was administered intravenously during a period of 3 minutes. The doses used have been shown to block effectively the influence of the autonomic nervous system on sinus nodal automaticity,[12,13] the effect of isoproterenol on ventricular refractoriness,[10] and the effect of vagal-induced changes on atrial refractoriness and sinus nodal automaticity.[14,15] The entire autonomic pacing protocol always was finished in less than 30 minutes.

All patients received both atropine and propranolol. In 6 patients propranolol was given first and electrophysiologic data were collected. These patients then received atropine and had the pacing studies repeated. Seven patients were given atropine first, and after the pacing studies were performed propranolol was given and pacing was repeated. Six patients received atropine and propranolol simultaneously, and electrophysiologic measurements were obtained only in the presence of both drugs.

Definitions: Q-T measured (Q-Tm) refers to Q-T intervals measured during sinus rhythm and 1:1 atrioventricular conduction. The mean of 10 complexes at a sinus rate that varied less than 5% was used. Q-T corrected (Q-Tc) refers to Q-T measured data that has been corrected for rate using Bazett's method; that is, $Q\text{-}Tc = Q\text{-}Tm/\sqrt{\text{sinus cycle length}}$. Q-T paced (Q-Tp) refers to the measured Q-T interval during constant atrial pacing. Sinus cycle length is the time in seconds between the P waves of 2 successive complexes. The sinus cycle length used in the calculation was the mean of 10 consecutive intervals.

Statistics: Statistical evaluation was performed on all measured and calculated points. Paired t analysis was used to compare effect of the drug on each measured interval. Analysis of variance was used when more than 2 groups were compared. Comparison of change from control was done by paired t test adjusted for multiple comparisons.[16]

Results

Patient groups: The patients were classified into 3 groups. All patients who received both propranolol and atropine constitute Group I (n = 20). Group II (n = 6) was a subset of Group I and included patients who received propranolol first followed by atropine. Group III (n = 7) was also a subset of Group I and represented patients who received atropine first followed by propranolol. Seven patients were given propranolol and atropine concomitantly. Patient characteristics are noted in Table I. Fourteen patients had no heart disease, 3 had coronary heart disease, and 3 had mitral valve prolapse. "No heart disease" was defined as no detectable structural heart disease identified by physical examination, electrocardiography, echocardiography, and left heart catheterization and coronary angiography.

Measured and paced Q-T interval: Table II and Figure 1 show the Q-T interval data during sinus and paced rhythm for all groups. Propranolol significantly ($p < 0.001$) increased the sinus cycle length in all Group II patients, but the mean measured Q-T interval changed insignificantly from 380 ± 18 to 372 ± 23 ms. In contrast, atropine significantly ($p < 0.01$) decreased sinus cycle length in all Group III patients and significantly shortened the mean measured Q-T interval from 360 ± 21 to 306 ± 24 ms ($p < 0.001$). After administration of propranolol plus atropine (Group I) the sinus cycle length decreased in all patients (836 ± 156 to 648 ± 84 ms, $p < 0.001$) and the mean measured Q-T interval shortened from 367 ± 26 to 329 ± 26 ms ($p < 0.001$).

Group I (n = 20) = patients who received atropine and propranolol; Group II (n = 6) = patients who received propranolol first; Group III (n = 7) = patients who received atropine first. A = atropine; A&P = atropine and propranolol; C = control; P = propranolol; p = Student's paired *t* test; PCL = paced cycle length; Q-T corrected = Q-Tm/√ sinus cycle length; Q-T measured = measured Q-T interval at the listed sinus cycle length; Q-T paced = measured Q-T interval at the listed paced cycle length; SX = standard deviation of X; X = arithmetic mean.

Corrected Q-T interval versus fixed atrial pacing: To allow for rate-independent Q-T interval assessment, we used Bazett's method and atrial pacing at a fixed cycle length. In Group II patients, the Q-T shortened from 428 ± 15 to 391 ± 22 ms ($p < 0.001$) using Bazett's method but did not change during atrial pacing (338 ± 28 to 345 ± 28 ms, difference not significant [NS]). The Q-T interval during atropine administration (Group III) significantly lengthened from 375 ± 29 to 418 ± 28 ms ($p < 0.01$) using Bazett's method, but substantially shortened from 376 ± 16 to 301 ± 15 ms ($p < 0.01$) during fixed atrial pacing. For all patients (Group I), propranolol plus atropine resulted in no change in the Q-T interval using Bazett's method (402 ± 33 to 411 ± 26 ms, p = NS). However, during atrial pacing the Q-T interval significantly shortened (330 ± 28 to 315 ± 27 ms, $p < 0.001$) in Group I patients. The changes from control in Q-T intervals during drug therapy are shown in Figure 1.

Ventricular effective refractory period: In 6 patients the ventricular effective refractory period was determined at the same paced cycle length as atrial pacing before and after administration of atropine plus propranolol, and the changes from control are depicted in Figure 1. For these patients the control ventricular effective refractory period was 241 ± 20 ms, and it decreased to 218 ± 21 ms ($p < 0.02$) after administration of atropine and propranolol. During atrial pacing the change in Q-T interval measured during atrial pacing after propranolol plus atropine administration was

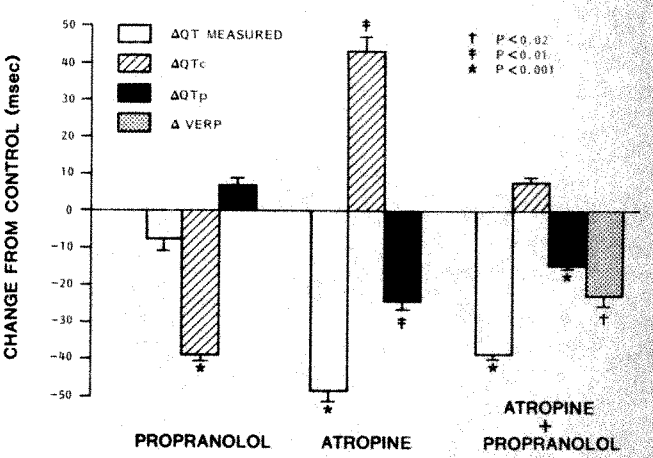

FIGURE 1. Effect of atropine and propranolol on Q-T interval. The change from control in the mean Q-T interval is plotted for each drug intervention. The change in corrected Q-T interval using Bazett's method occurs in the opposite direction than either measured or paced Q-T interval data. The direction of change in ventricular effective refractory period after atropine plus propranolol administration is similar to measured and paced Q-T interval changes. ΔQ-T measured = measured Q-T interval after drug minus measured Q-T interval during control; ΔQ-Tc = ΔQ-T measured corrected for rate using Bazett's method; ΔQ-Tp = Q-T interval at a fixed atrial pacing rate after drug minus Q-T interval at the same atrial pacing rate during control; ΔVERP = ventricular effective refractory period after drug minus ventricular effective refractory period during control. Significance levels refer to changes from control.

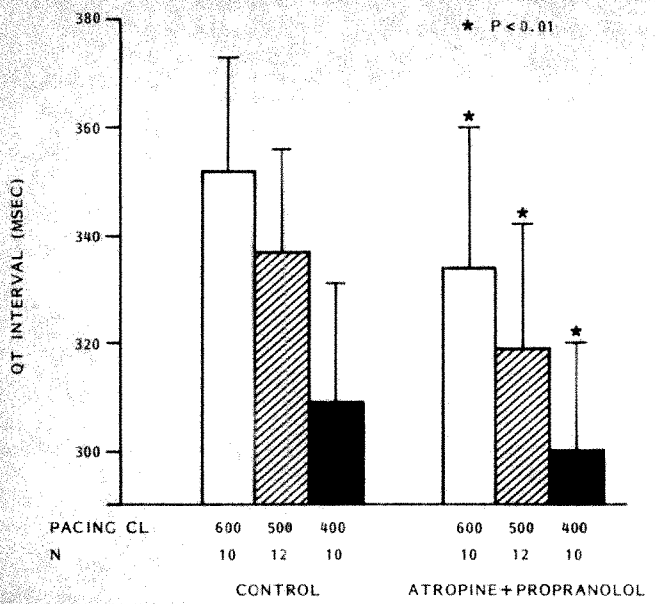

FIGURE 2. Change in Q-T interval after administration of atropine and propranolol as a function of heart rate. Each group was paced at the listed pacing cycle length (CL). The Q-T interval significantly ($p < 0.01$) shortened from control in each group after administration of atropine plus propranolol. The magnitude of change for each pacing rate is similar to the magnitude of change at any other pacing rate.

consistent with the changes in ventricular refractoriness. However, the Q-T interval corrected for rate by Bazett's formula increased rather than decreased when atropine and propranolol were given. Similar discordance between the Q-T interval measured during atrial pacing and calculated using Bazett's formula was noted during single drug intervention with either propranolol or atropine (Fig. 1).

Role of pacing rate: Although all Q-T measurements during atrial pacing were made at the same atrial pacing rate before and during drug intervention, the rate varied among patients. Figure 2 shows the mean data for Group I patients at paced rates of 600, 500, and 400 ms. Statistical analysis of the change in Q-T interval at each rate during drug intervention demonstrated no difference among the 3 rates used (that is, the magnitude of change in the Q-T interval from the control value was similar regardless of the rate tested).

Discussion

Bazett's formula for correcting the Q-T interval for heart rate: Our data clearly depict the difficulty in using a correction factor to assess Q-T interval when evaluating drugs that affect both heart rate and Q-T interval. This problem was first noted in Bazett's original report[3] in 1920. Using his formula $Q\text{-}T = K\sqrt{\text{R-R interval}}$, Bazett calculated the effect of sectioning the vagus in dogs from data collected by Einthoven[17] in 1908. He found that the K value increased after vagal section and decreased with vagal stimulation. Since that time a number of formulas have been developed to reflect more accurately the change in Q-T interval caused by heart rate.[2,4,5,18–20] No formula has been developed to permit assessment of drug effect on the Q-T interval. Simonson et al.[4] further defined the relation of the Q-T to the R-R interval and found that it also was related to the patient's age. He stated that all currently used formulas were applicable only between rates of 50 to 115 complexes/min and that the effect of exercise on Q-T interval was unknown. Recently, atrial pacing to fix the heart rate has been used to evaluate the changes in Q-T interval caused by propranolol. It was shown that Bazett's formula predicted a shortening in Q-T interval, although at identical atrial pacing rates the Q-T interval did not change significantly.[8,9]

Correction for the Q-T interval using Bazett's formula proved misleading when either atropine or propranolol was given. Atropine actually significantly shortens the Q-T interval measured during atrial pacing, whereas Bazett's formula predicts that the Q-T interval lengthens when corrected for rate. Atropine also shortens the ventricular effective refractory period.[10] In addition, both propranolol and propranolol plus atropine produced measured Q-T intervals inconsistent with those predicted by Bazett's formula.

Role of atrial pacing: Atrial pacing permits comparison of ventricular changes in depolarization and repolarization without relying on a rate correction formula. Bazett's formula has been shown to be unreliable at slow or fast heart rates.[4] Propranolol significantly slowed the heart rate and atropine significantly increased the heart rate. Additionally, atropine had a direct effect on shortening on Q-T interval. These factors, in combination with other effects, may contribute to the differences found between the Q-T interval measured during pacing and the Q-T interval corrected for rate by Bazett's formula.

The ventricular effective refractory period, an independent measure of repolarization, was determined in 6 patients before and after atropine and propranolol administration. The changes in refractoriness mirrored the change in paced Q-T interval but was discordant with the change in corrected Q-T interval using Bazett's formula. It has previously been shown that the ventricular effective refractory period does not change when propranolol is given but shortens with administration of atropine and atropine plus propranolol.[10] These data totally agree with the paced Q-T data, indirectly corroborating the drug effects on ventricular repolarization noted in this study.

Implications: The Q-T interval is the electrocardiographic approximation of ventricular depolarization and repolarization throughout the heart and may not accurately reflect individual electrophysiologic changes in all areas of the ventricles. Thus, although autonomic blockade shortened both Q-T interval and right ventricular refractoriness at the apex, it is possible that ventricular refractoriness did not change or even lengthened at other ventricular sites, such as those af-

fected by regional ischemia or scar due to tissue inhomogeneity. This limitation applies to all studies in which the effect of a drug or other intervention is tested at only 1 site, the usual method used in man.

In conclusion, resting parasympathetic tone appears to affect directly the Q-T interval in man, and withdrawal of vagal tone shortens the Q-T interval. Further, vagal influence on the ventricle as measured by change in the Q-T interval may be measured from the surface electrocardiogram only when the heart rate is fixed as in atrial pacing. Bazett's formula may be misleading when applied to drugs that affect both heart rate and Q-T interval directly.

Subcostal M-Mode Echocardiography of the Right Atrial Wall in the Diagnosis of Cardiac Arrhythmias

NIKSA DRINKOVIC, MD

The M-mode echocardiogram of the right atrial (RA) wall can be easily recorded in each person from the subcostal location. In a normal RA wall motion pattern, atrial contraction is represented by a markedly prominent posterior motion. The presence or absence of atrial contractions in the subcostal RA wall echocardiogram, their amplitude, and their timing may help in the diagnosis of cardiac arrhythmias with the simultaneously recorded nondiagnostic electrocardiogram. Flat and hidden P waves can be accurately identified throughout the cardiac cycle. It is possible to distinguish between atrial, ventricular, and nodal premature beats and to recognize atrial fibrillation, atrial flutter, paroxysmal atrial tachycardia, paroxysmal atrial tachycardia with block, atrioventricular (AV) nodal tachycardia, and supraventricular tachycardias with aberrant ventricular conduction. The diagnosis of wandering pacemaker, AV dissociation, sinoatrial block, and AV block is facilitated.

On the basis of study of 60 patients with various rhythm disturbances, it was concluded that analysis of the subcostal RA wall echocardiogram is a new, helpful noninvasive approach in the diagnosis of cardiac arrhythmias.

Several echocardiographic studies[1–8] have assessed the applicability of M-mode echocardiography in the analysis of cardiac arrhythmias. It has been demonstrated that the abnormalities associated with the motion of various cardiac structures could have diagnostic implications in certain rhythm disturbances. However, the subcostal RA wall echocardiogram has not been used in the detection of cardiac arrhythmias. The purpose of this report is to describe the advantages of analyzing RA wall motion patterns in subcostal M-mode recordings to aid in the diagnosis of cardiac arrhythmias.

Methods

Patients: Sixty patients with various rhythm disturbances were studied by electrocardiography and subcostal M-mode echocardiography. Intracardiac electrophysiologic studies were also carried out in a few patients. The electrocardiogram revealed sinus arrhythmia and wandering pacemaker in 8, atrial, ventricular, and atrioventricular (AV) nodal premature beats in 20, atrial fibrillation in 10, atrial flutter in 6, AV nodal rhythm, supraventricular paroxysmal tachycardia, and atrial tachycardia with block in 8, sinoatrial block in 2, and AV dissociation and various degrees of AV block in 16 patients.

Echocardiography: Echocardiograms were performed with a commercially available ultrasonic device utilizing the 2.25 MHz transducer. Lead II of the electrocardiogram and occasionally a phonocardiogram were recorded simultaneously. The paper speed was 2.5, 5, and 7.5 cm/s.

The transducer was placed in the subxiphoid area slightly to the patient's right and directed toward the middle of the right clavicle. The RA wall is easily recorded from this location in each person. Slight changes of the transducer angulation are then necessary to obtain maximal atrial wall motion amplitude, but the recording should be made under the constant angle of the ultrasonic beam.

Results

Normal right atrial motion: While performing the subcostal M-mode study in patients with transvenous right ventricular pacing catheters, it was observed that the RA wall can be easily and quickly recorded in each patient.[9] This was later confirmed in more than 150 routine echocardiographic examinations.

Normal right RA wall motion has a characteristic pattern in a subcostal M-mode echocardiogram. The wall moves anteriorly during ventricular systole, at

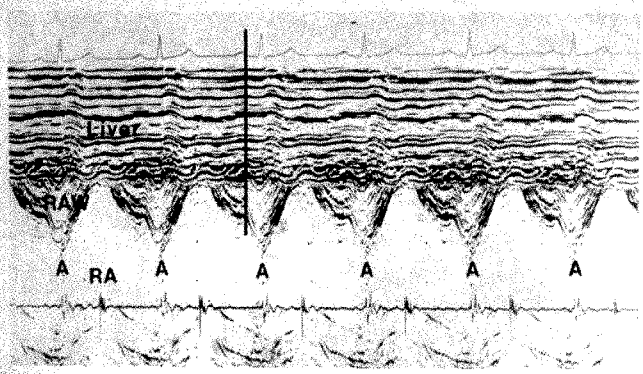

FIGURE 1. Subcostal M-mode echocardiogram of the right atrial wall (RAW) in a normal subject. Atrial contractions (A) start at the nadir of the P wave and before the first heart sound. RA = right atrium.

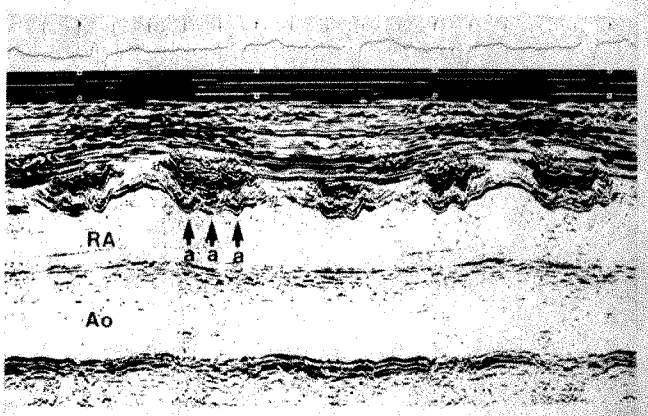

FIGURE 2. Subcostal right atrial wall echocardiogram in a patient with coarse atrial fibrillation waves on the electrocardiogram. Their counterparts in the echocardiogram are small amplitude atrial contractions (a). Ao = aorta; RA = right atrium.

which time the tricuspid valve is closed and the right atrium fills with blood. With the opening of the tricuspid valve, the RA wall rapidly moves posteriorly. A plateau occurs throughout the remaining ventricular diastole ending with atrial contraction that is presented as a prominent posterior motion (Fig. 1). Atrial contraction starts on the nadir of the P wave in the electrocardiogram and cannot be mistaken for the right ventricular wall contraction that begins at the nadir of the R wave.

The presence or absence of atrial contractions in a subcostal right atrial wall echocardiogram, their amplitude, and their timing might help in the diagnosis of cardiac arrhythmias in doubtful cases with nondiagnostic electrocardiograms. Each arrhythmia has a specific RA wall motion pattern.

Atrial fibrillation and flutter: Atrial fibrillation is characterized by the absence of atrial contraction. Fine atrial fibrillation does not cause any significant oscillatory movement in the right atrial wall echocardiogram. In contrast, coarse fibrillary waves are demonstrated as small amplitude atrial contractions, usually better visualized during ventricular diastole (Fig. 2).

Figure 3 illustrates the echocardiographic pattern of atrial flutter with a 2:1 atrioventricular block. Flutter waves are not discernible in the electrocardiogram because of superimposed QRS and T waves. On the contrary, flutter contractions and their rate (320/min) are clearly demonstrated in the RA wall echocardiogram.

Premature beats: Figure 4 shows an atrial premature beat with aberration of the QRS. The P wave is superimposed on the peak of the T wave of the preceding beat, and this is well documented by an atrial contraction in the RA wall echocardiogram. Similarly, the P waves lost in the T waves and QRS complex can be easily detected in the subcostal RA echocardiogram, as seen in the example of a patient with a functioning ventricular pacemaker (Fig. 5).

The echocardiographic pattern of 2 nodal beats is illustrated in Figure 6. It is obvious that the atrium and

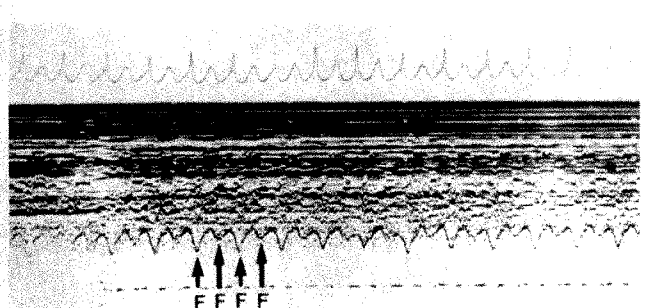

FIGURE 3. Subcostal RA wall echocardiogram of a patient with atrial flutter. Flutter contractions (F) are clearly visible and are of higher amplitude than fibrillatory contractions. Contractions indicated with **long arrows** are of small amplitude when occurring during ventricular systole.

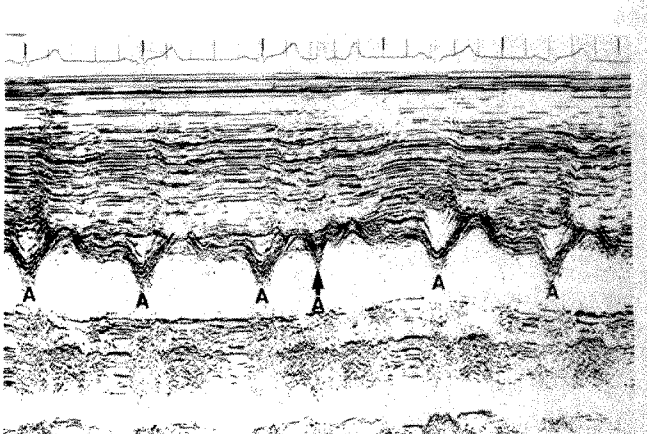

FIGURE 4. Subcostal RA wall echocardiogram of a patient in sinus rhythm and ectopic atrial beat with aberrant ventricular conduction. Fourth P wave is premature and indistinct because of superimposition on the T wave of the preceding beat. It is well recognized in the echocardiogram by the presence of a premature atrial contraction (**arrow**). A = atrial contraction.

ventricle contract simultaneously. As can be seen from the distorted atrial filling curve, an abortive atrial contraction occurs during ventricular systole. At the same time, atrial filling diminishes considerably. The second beat is an atrial premature beat with aberrant ventricular conduction, as indicated by the preceding atrial contraction in the echocardiogram.

Recognition of a ventricular premature beat is more accurate in the atrial echocardiogram than in the electrocardiogram because the absence of the preceding atrial contraction can be better demonstrated (Fig. 7, top). Abortive atrial contraction is always visualized when a P wave of sinus origin is lost in the QRS of the ventricular extrasystole (Fig. 7, bottom). However, retrograde activation of the atria is highly probable if atrial contractions are premature and occur repeatedly at the same distance after ventricular extrasystoles.

Paroxysmal supraventricular tachycardia: Figure 8 (top) illustrates an unsuccessful attempt to terminate paroxysmal supraventricular tachycardia by right ventricular overdrive pacing. Supraventricular tachycardia is presented by the fast rate of atrial contractions that diminish in amplitude during pacing while the atrium contracts against the closed tricuspid valve. Atrial contractions caused by retrograde conduction on a 1:1 ratio always exhibit a characteristic zigzag pattern. Figure 8 (bottom) demonstrates the successful termination of atrial tachycardia in the same patient. After the interruption of pacing, sinus rhythm resumed as seen from the normal right atrial motion pattern.

Figure 9 illustrates the echocardiographic pattern of paroxysmal atrial tachycardia with 2:1 atrioventricular block. Some P waves are indistinguishable in the electrocardiogram, but all atrial contractions are visible in the echocardiogram. They are small in amplitude, particularly those occurring during ventricular systole and differ from flutter contractions in their rate. However, all contractions exhibit sufficient anterior motion to be recorded and no false-positive results were observed in any patient. Unlike sinus rhythm, the peak of the atrial contractions is simultaneous with the P waves. This probably occurs because of the altered distance between the ectopic focus and the recorded part of the right atrium.

AV dissociation and block: The practical value of the subcostal RA wall echocardiogram in detecting AV dissociation is demonstrated in Figure 10. Prompt recognition of independence between atrial and ven-

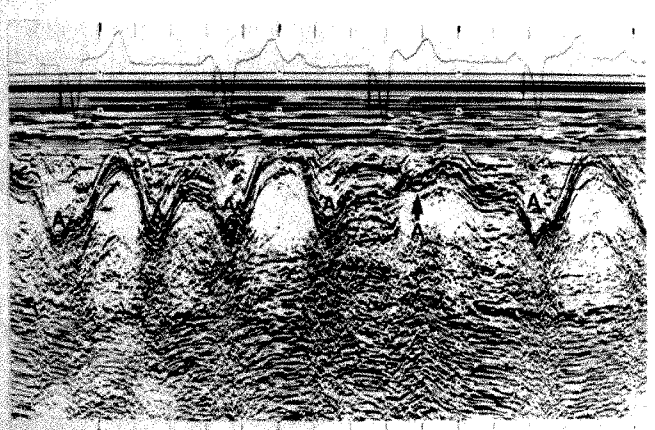

FIGURE 5. Subcostal echocardiogram of the RA wall of a patient with sinus rhythm and functioning ventricular pacemaker. P waves hidden in T wave and QRS complexes are recognized by corresponding atrial contractions (A). The fifth atrial contraction (**arrow**) has a small amplitude when occurring during ventricular systole.

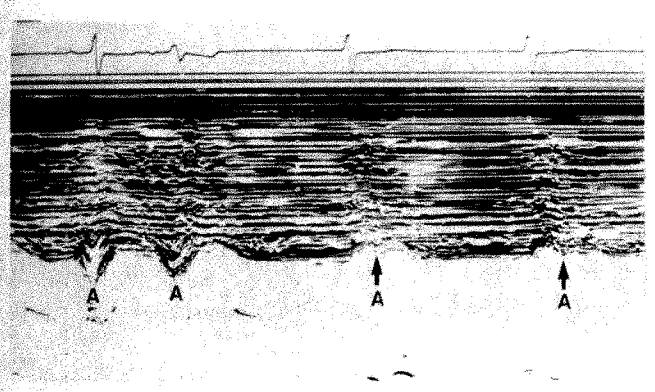

FIGURE 6. Subcostal RA wall echocardiogram in a patient with AV nodal rhythm. Nodal beats (third and fourth) are characterized by abortive atrial contraction (**arrow**) which occurs during ventricular systole. The second beat is preceded by atrial contraction and represents an atrial premature beat with aberrant ventricular conduction. A = atrial contraction.

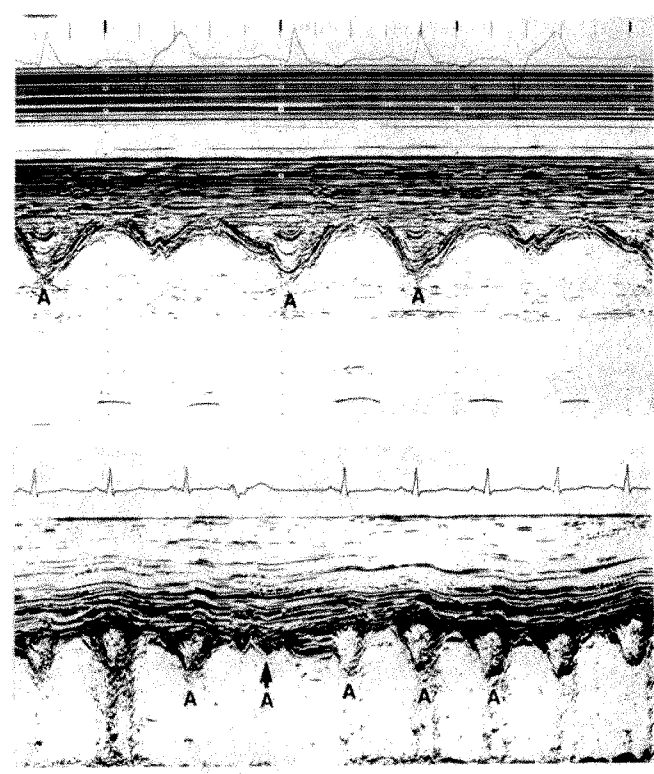

FIGURE 7. Top, subcostal RA wall echocardiogram of a patient in sinus rhythm with ventricular premature beats (second and fifth) which are recognized by the absence of preceding atrial contractions (A). **Bottom,** P wave hidden in the QRS of ventricular extrasystole presented as an abortive contraction (**arrow**).

tricular activity is possible because all atrial contractions are visible in the echocardiogram. Figure 11 presents a subcostal RA wall echocardiogram in a patient with complete AV block and sinus rhythm.

A subcostal RA wall echocardiogram might be helpful in studying the function of an implanted atrial pacemaker as seen in Figure 12, where improper atrial pacing is demonstrated.

Discussion

In previous studies,[10,11] it was shown that analysis of abnormalities associated with the motion of the cardiac valves, the aortic root, the right ventricular anterior wall, the ventricular septum, and the left atrial and left ventricular walls, helped identify atrial premature beats, atrial fibrillation, atrial flutter, and AV block. The existence of cannon waves in the neck veins and their regular or irregular occurrence may also support the diagnosis of AV nodal rhythm, complete AV block, and ventricular tachycardia.[12]

Advantages of subcostal RA echocardiogram: Analysis of the subcostal RA wall echocardiogram has several advantages in the diagnosis of cardiac arrhyth-

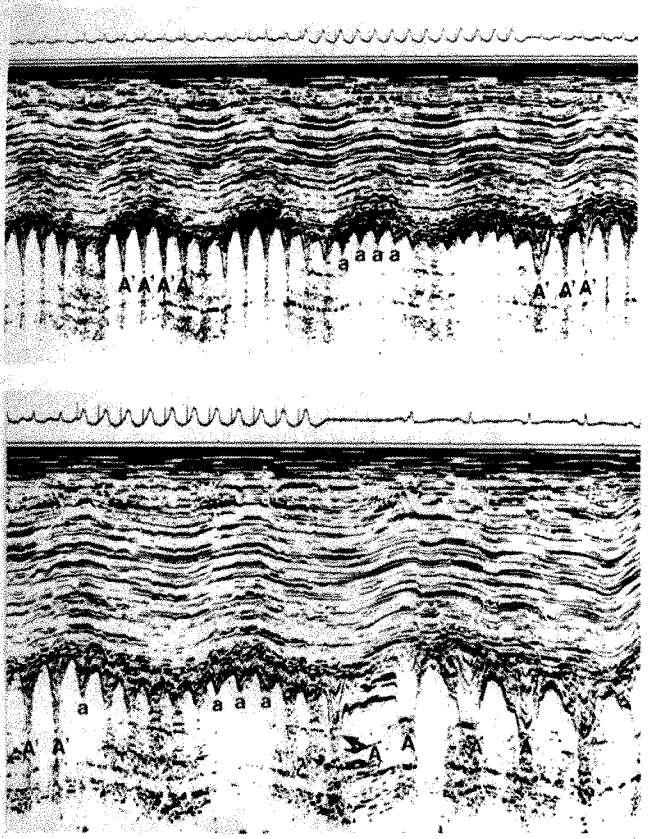

FIGURE 8. Top, subcostal RA wall echocardiogram obtained in a patient with supraventricular paroxysmal tachycardia presented by a fast rate of atrial contractions (A'). Atrial contractions (a) diminish in amplitude during ventricular overdrive pacing, when occurring during ventricular systole. After cessation of pacing, tachycardia reappears. **Bottom,** successful termination of tachycardia in the same patient. Interruption of pacing is followed by blocked atrial contraction (**arrow**) and short atrial standstill after which sinus rhythm resumes. A = normal atrial contraction.

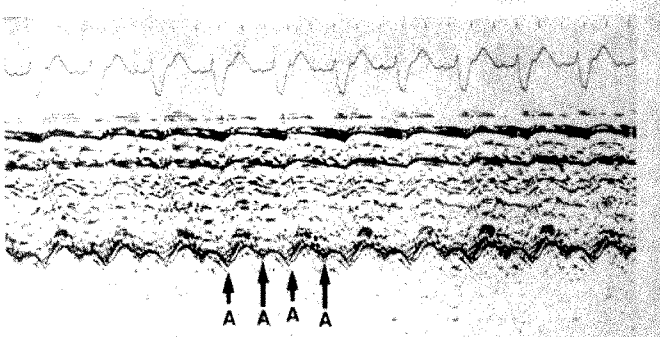

FIGURE 9. Subcostal RA wall echocardiogram of a patient with paroxysmal atrial tachycardia with block. All atrial contractions (A) are visible in the echocardiogram. Those indicated with the **long arrows** are of smaller amplitude when occurring against the closed tricuspid valve.

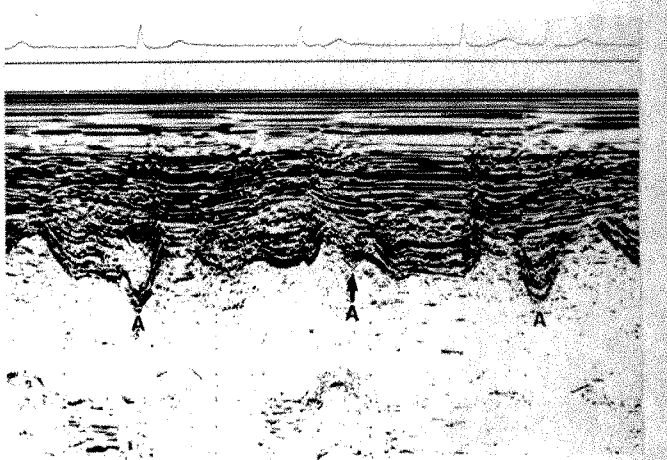

FIGURE 10. Subcostal RA wall echocardiogram in a patient with AV dissociation. The changing relation between atrial contractions (A) and QRS complexes is demonstrated. Contraction indicated by the **arrow** is aborted when occurring during ventricular systole.

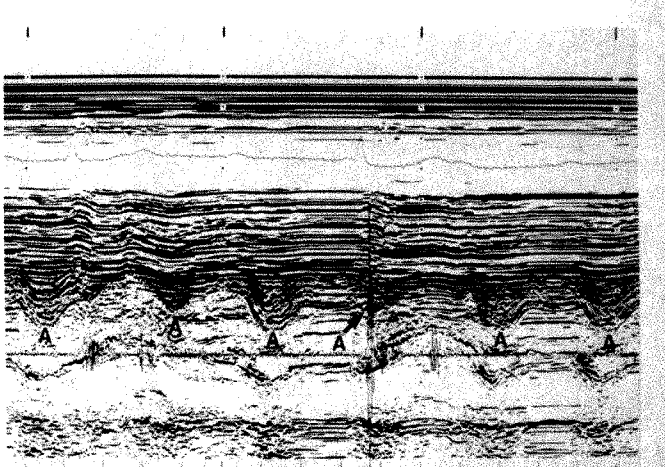

FIGURE 11. Subcostal RA wall echocardiogram of a patient with complete AV block. Atrial contractions (A) are easily recognized and are of smaller amplitude when occurring during ventricular systole (**arrow**).

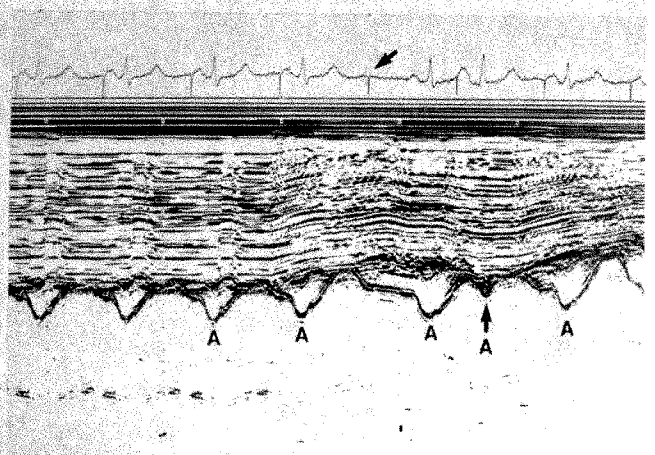

FIGURE 12. Subcostal RA wall echocardiogram obtained during temporary atrial pacing. The pacemaker spike indicated by the **arrow** did not cause atrial depolarization and is not followed by atrial contraction (A) in the echocardiogram. The sixth atrial contraction (**upward arrow**) is aborted when occurring during ventricular systole.

mias compared with the aforementioned techniques. A clear detection of atrial contraction in the subcostal RA wall echocardiogram is possible throughout the cardiac cycle during ventricular systole and diastole. The normal RA wall contraction is presented as a high amplitude posterior excursion in the subcostal echocardiogram. On the other hand, in the echocardiogram of the left atrial posterior wall, whose motion is often difficult to demonstrate, atrial systole causes only a slight anterior deflection.[13] It is of practical importance that the subcostal echocardiogram of the RA wall can be easily recorded in each person while the quality of the recording is not influenced by hyperinflation of the lungs.

This technique allows the clear detection of small voltage P waves, P waves hidden in the T waves or lost in the QRS complexes, and is superior in this respect to special chest leads and esophageal electrocardiography. The presence or absence of atrial contractions and their amplitude or timing give each arrhythmia a specific RA wall motion pattern which is helpful in their recognition with a simultaneously recorded nondiagnostic electrocardiogram.

Application to diagnosis of cardiac arrhythmias: It is therefore possible to distinguish between atrial, ventricular, and nodal premature beats and to recognize atrial fibrillation, atrial flutter, paroxysmal atrial tachycardia, paroxysmal atrial tachycardia with block, and AV nodal tachycardia. The diagnosis of a wandering pacemaker, sinoatrial block, AV dissociation, and all degrees of AV block is facilitated. Although there was no opportunity to study patients with ventricular tachycardia, it is obvious that this technique is useful in differentiating supraventricular tachycardias with aberrant ventricular conduction from ventricular tachycardia. However, it does not help differentiate between ventricular premature beats and aberrant conduction of supraventricular impulses or between AV nodal and ventricular tachycardia, when atrial fibrillation coexists.

Subcostal RA wall echocardiographic analysis may also be of use in controlling the function of atrial pacemaker. Information regarding atrial contractility before and after institution of atrial pacing can be obtained.

Study of RA hemodynamics: Some observations of RA hemodynamics were made. In a few patients with large pericardial effusion, exaggerated RA wall motion was documented. In contrast, patients with constrictive pericarditis and some with heart failure have diminished motion amplitude with a change in the duration of various phases of the atrial cycle. We are currently investigating the association of these changes with the height of the right heart and pulmonary arterial pressures and believe that the noninvasive prediction of these pressures will be possible to some extent.

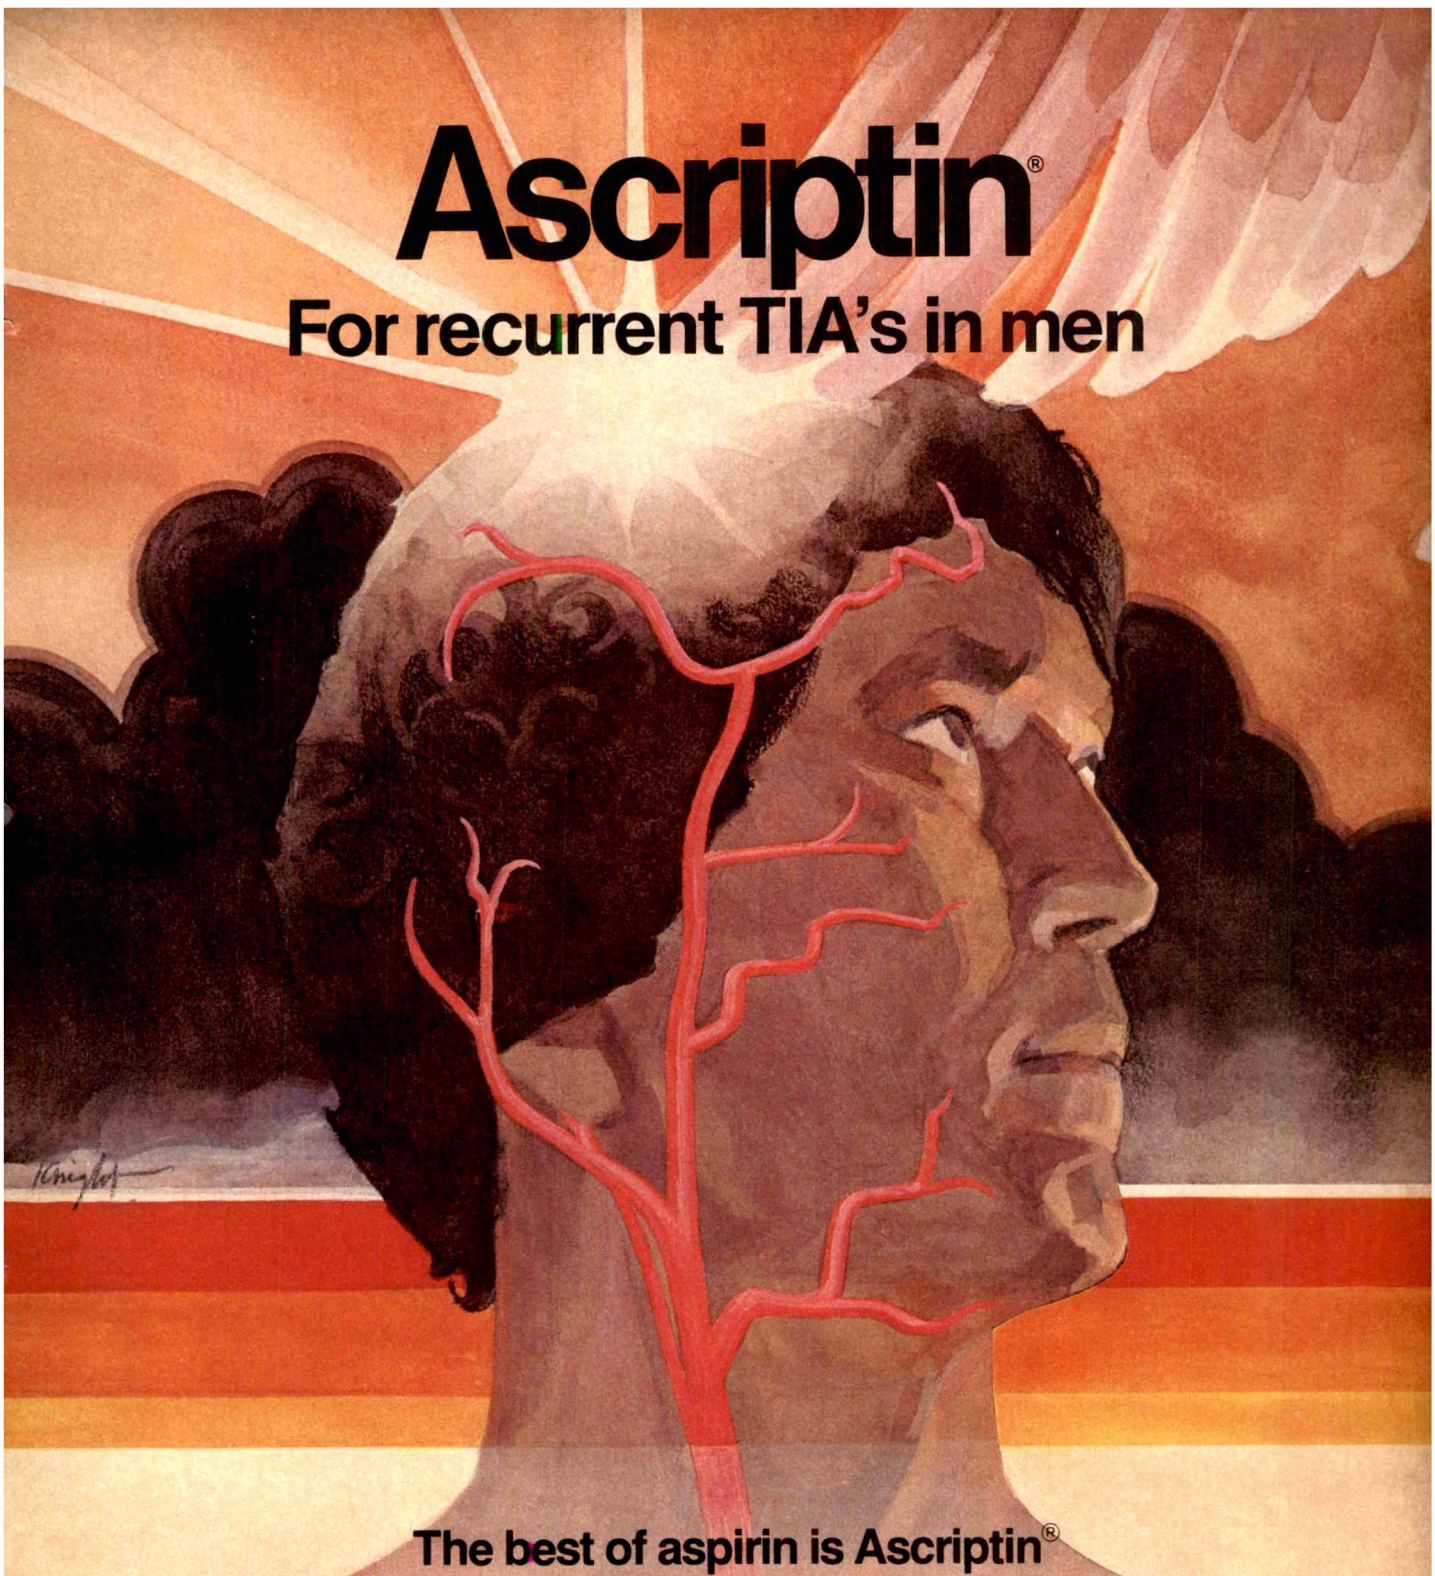
Ascriptin®

For recurrent TIA's in men



The best of aspirin is Ascriptin®

Indications: For reducing the risk of recurrent transient ischemic attacks (TIA's) or stroke in men who have had transient ischemia of the brain due to fibrin platelet emboli. There is inadequate evidence that aspirin or buffered aspirin is effective in reducing TIA's in women at the recommended dosage. There is no evidence that aspirin or buffered aspirin is of benefit in the treatment of completed strokes in men or women.

Precautions: (1) Patients presenting with signs and symptoms of TIA's should have a complete medical and neurologic evaluation. Consideration should be given to other disorders which resemble TIA's. (2) Attention should be given to risk factors: it is important to evaluate and treat, if appropriate, other diseases associated with TIA's and stroke such as hypertension and diabetes. (3) Concurrent administration of absorbable antacids at therapeutic doses may increase the clearance of salicylates in some individuals. The concurrent administration of nonabsorbable antacids may alter the rate of absorption of aspirin, thereby resulting in a decreased acetylsalicylic acid/salicylate ratio in plasma. The clinical significance on TIA's of these decreases in available aspirin is unknown.

Dosage: 1300 mg a day, in divided doses of 650 mg twice a day or 325 mg four times a day.

DIABETES MELLITUS

From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- The causes of diabetic inheritance
- Immune factors of diabetes
- Mechanisms of diabetes (The culmination of 50 years of research)
- Autoimmunity
- New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- New developments in the treatment of diabetes
- Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- Pharmacology of oral hypoglycemics
- Use of insulin infusion devices
- Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

Intracoronary Infusion

American Edwards Takes the Technology Further Than Ever Before

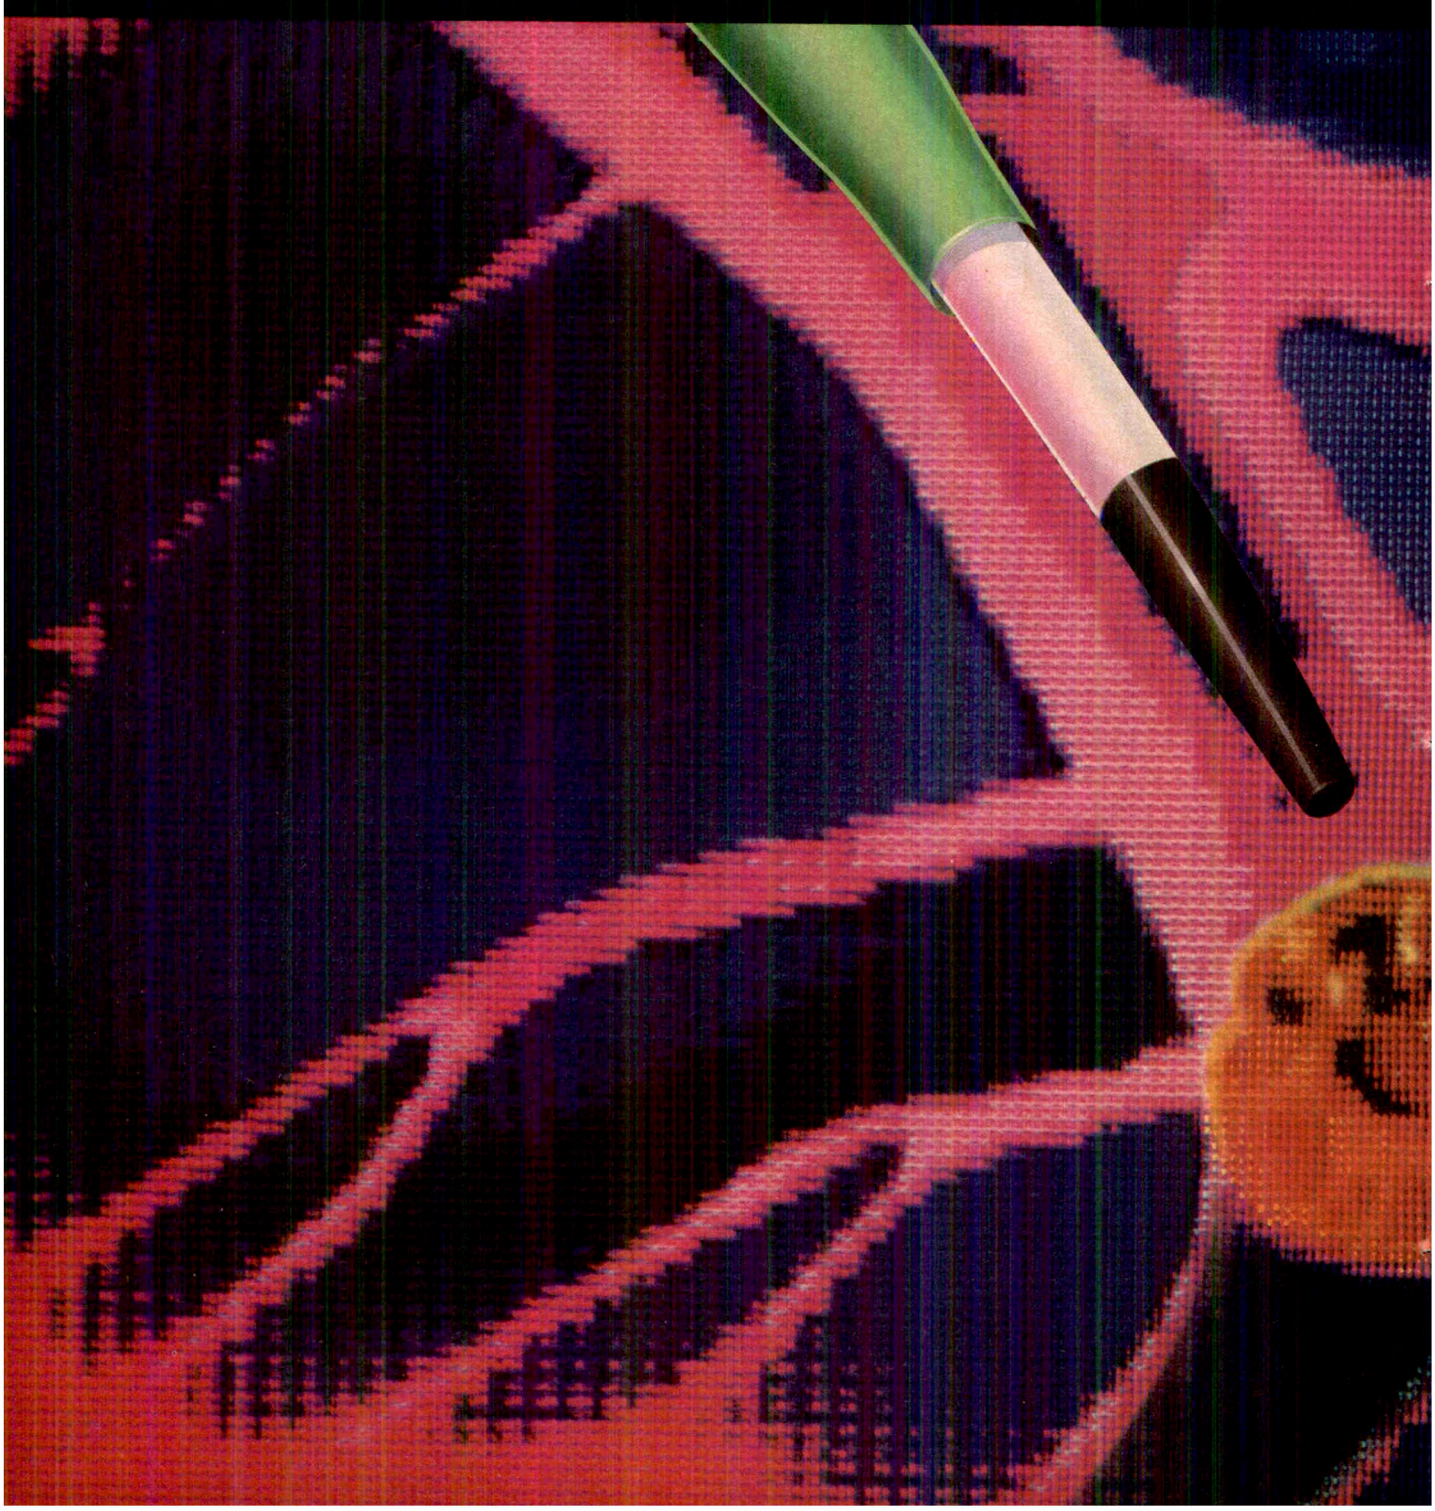
With over a million myocardial infarcts in the U.S. every year and an associated 30 percent mortality rate, researchers have begun concentrating their efforts on drug lysis of intracoronary thrombi as a promising new avenue of patient management.[1,2]

Introducing the Ganz-Edwards™ Coronary Infusion Catheter
Advancement of the Coronary Infusion Catheter through an angiography catheter, already in place at the ostium, permits drug infusion inside the coronary arteries at the exact site of the clot.

Because delivery is so specific, drug dilution is minimized. Shunting of the thrombolytic agent away from the target area into proximal branches is dramatically reduced.[3]

Concentration of the thrombolytic agent at the target area substantially accelerates clot lysis, so critical in myocardial salvage.[3]

Pressure Monitoring Combined with a Radiopaque, Atraumatic Tip
With sub-selective coronary infusion at the forefront of technology, the Ganz-Edwards Coronary Infusion Catheter improves the technique with these added benefits:



] An atraumatic distal 20 cm for safer
vancement into distal locations of the
ronary vasculature.
] A reduced lumen size for continuous
essure monitoring and contrast injection
rough the angiography catheter, without
usion interruption.
] A radiopaque distal tip with a level of
sibility that is unsurpassed.

inging Concept and
chnology Together

r over 25 years, American Edwards has
en merging promising concepts in critical care medicine, with the technology to make those ideas tangible.

From heart valve replacement, to hemodynamic monitoring, to sub-selective coronary infusion…helping you improve the quality of life is what we're all about.

Mary Allen Engle, M.D.
Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure...a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

SLOW-K® potassium chloride slow-release tablets

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS
Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

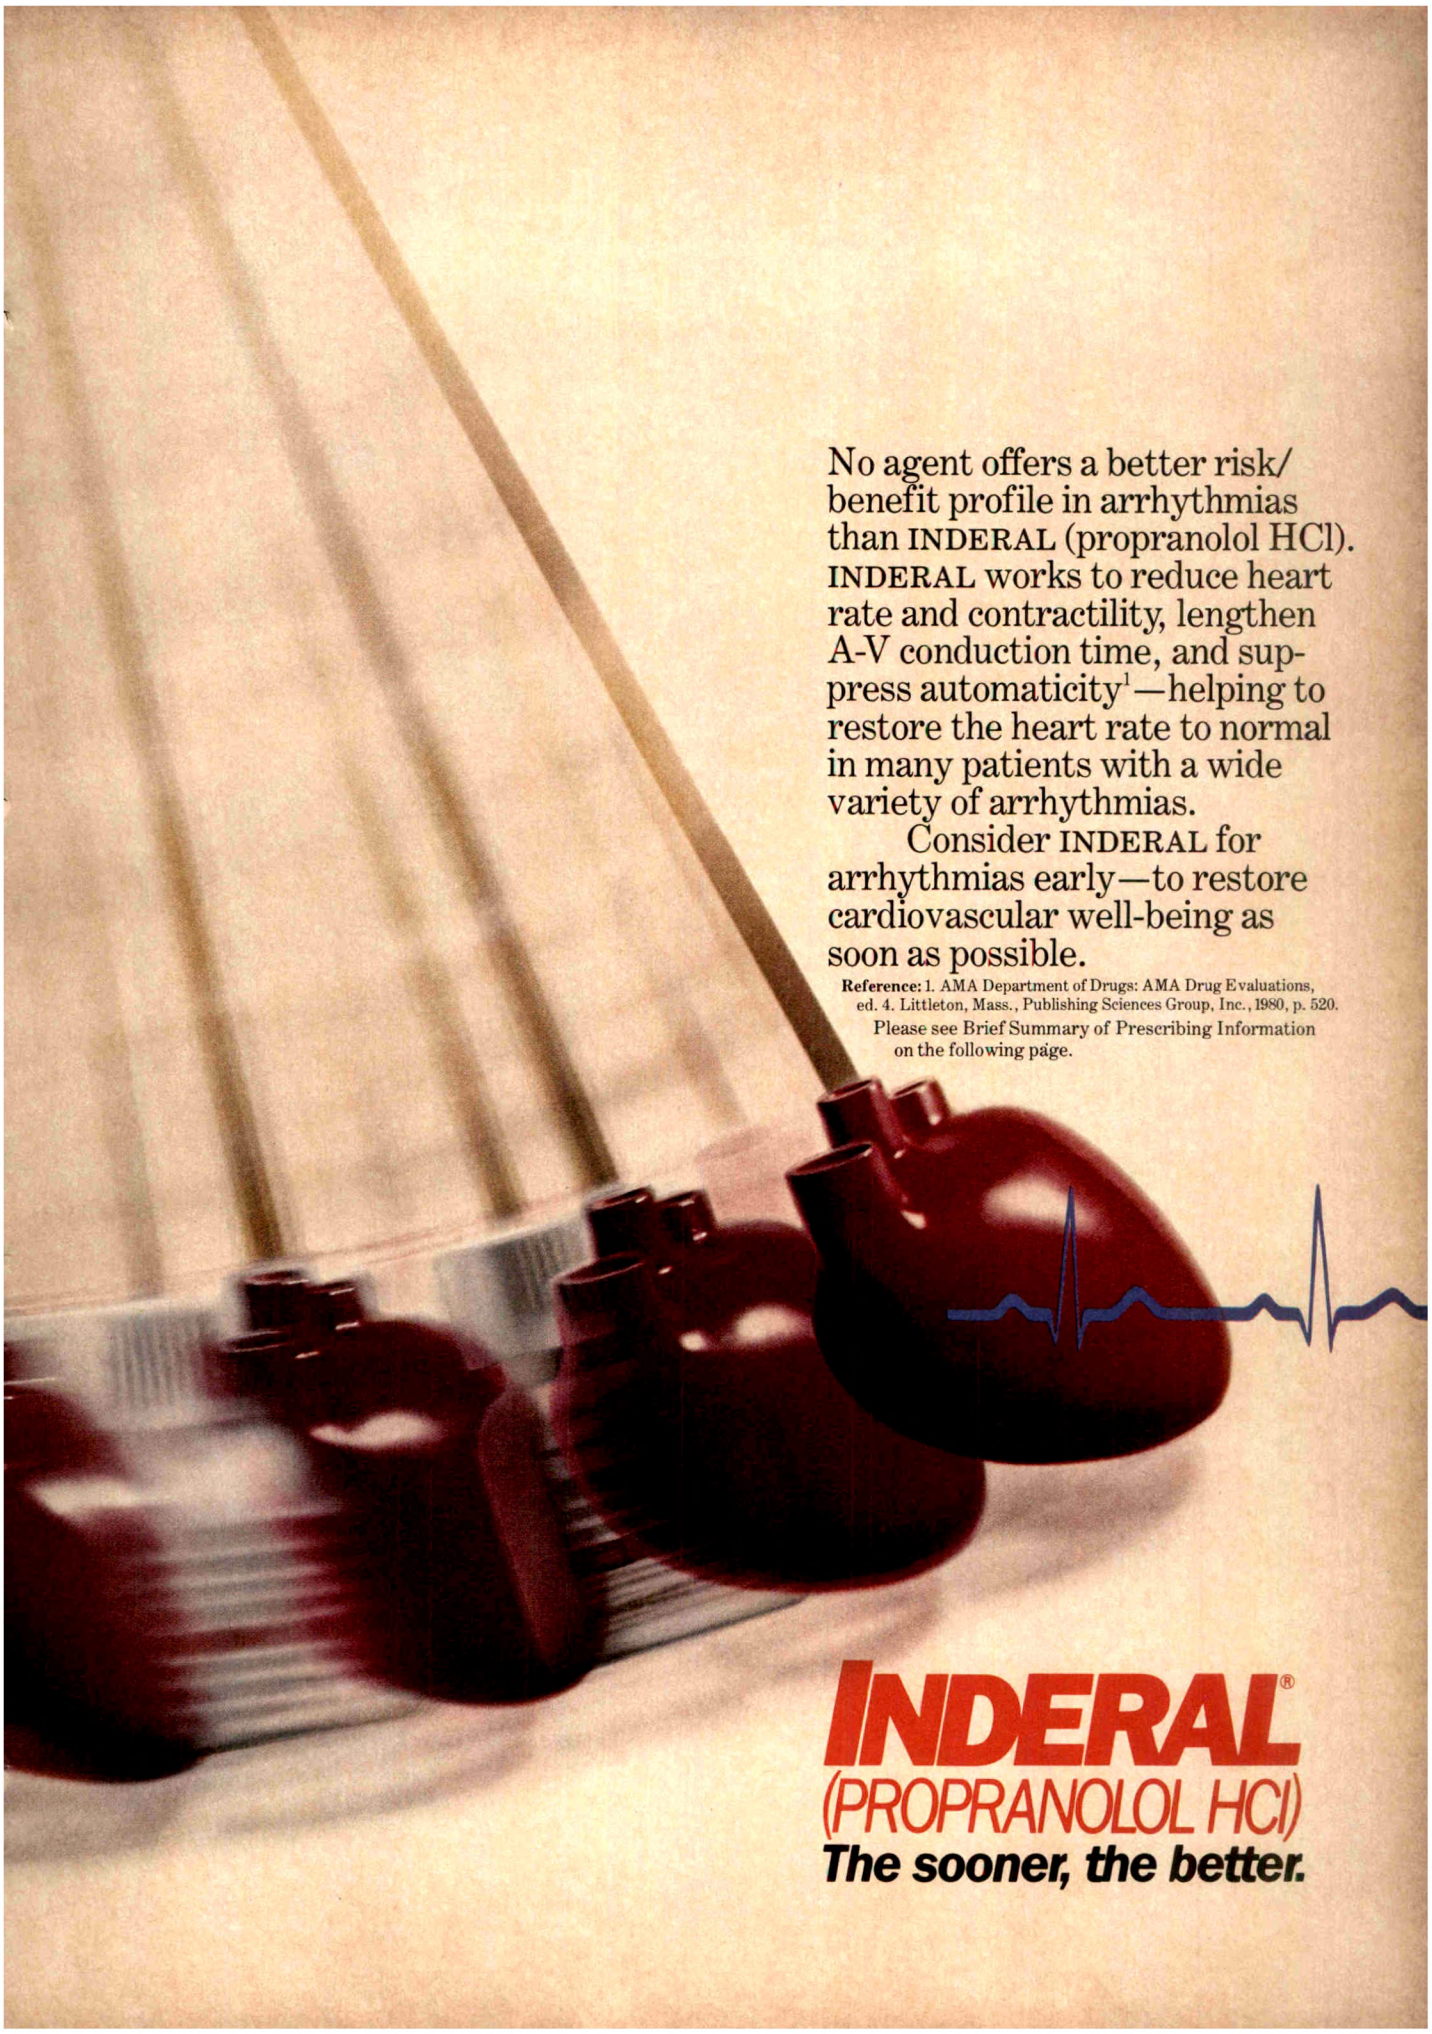
ARRHYTHMIAS
Cardiovascular well-being often begins with Inderal®
(PROPRANOLOL HCl)
Inderal®
(propranolol hydrochloride)
10 mg
100 Tablets
Ayerst
AYERST LABORATORIES INC.



No agent offers a better risk/benefit profile in arrhythmias than INDERAL (propranolol HCl). INDERAL works to reduce heart rate and contractility, lengthen A-V conduction time, and suppress automaticity[1]—helping to restore the heart rate to normal in many patients with a wide variety of arrhythmias.

Consider INDERAL for arrhythmias early—to restore cardiovascular well-being as soon as possible.

Please see Brief Summary of Prescribing Information on the following page.

INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.

INDERAL®
(PROPRANOLOL HCl)

To restore cardiovascular well-being.

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia, congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C)

Application of Body Surface Mapping to Exercise Testing: S-T_{80} Isoarea Maps in Patients With Coronary Artery Disease

FRANK G. YANOWITZ, MD, G. MICHAEL VINCENT, MD, ROBERT L. LUX, PhD, MAHESH MERCHANT, PhD, LARRY S. GREEN, MD, and J. A. ABILDSKOV, MD

Body surface electrocardiographic maps were recorded before and after exercise in 25 men with angiographically documented coronary disease. Torso potential distributions at 192 locations were derived from a 32 lead electrode array using methods previously described in our laboratory. The S-T segment was characterized by the spatial distribution of the integral of S-T segment voltage over 80 ms (S-T_{80}). Body surface regions where the S-T_{80} areas were −8 mV·ms or greater were identified in 18 of 25 patients. The most negative S-T_{80} site on the map was called the "S-T_{80} minimum." The S-T_{80} minima were located 1 or 2 electrode rows away from the standard V_4–V_6 electrode positions in 6 of 18 patients who developed S-T_{80} areas of −8 mV·ms or greater. Our data suggest that standard electrocardiographic leads may not be optimal for identifying S-T segment depression in all patients with coronary disease. Furthermore, body surface mapping during exercise provides a more quantitative and qualitative method for characterizing the ischemic response to exercise.

The electrocardiographic response to exercise has established value for detection of ischemic heart disease.[1–7] However, it is uncertain that the usual leads employed for this purpose are optimal. Although precordial leads V_4–V_6 or a modified V_5 are most likely to show S-T segment displacement during ischemia, approximately 10% of patients with ischemia due to coronary disease have S-T segment changes only in other leads.[8] Therefore, more extensive sampling of the electrocardiogram may result in improved detection of myocardial ischemia and may also be useful in assessing the location and severity of coronary artery disease. This possibility is supported by the recent work of Fox et al.[9] employing a 16 electrode precordial grid during exercise testing. The potential for increased sensitivity and assessment of lesion location and severity makes it desirable to further evaluate more complete sampling of the body surface electrocardiogram in association with exercise testing.

Miller et al.[10] and Mirvis[11] reported results of body surface mapping with exercise in normal subjects and contributed to the development of appropriate methodology. The present study was carried out with the general objectives of further developing methodology and beginning an evaluation of clinical utility of body surface mapping during exercise testing. The specific purpose of this study was to determine whether standard precordial leads V_4–V_6 adequately sample the body surface distribution of S-T segment displacement due to ischemia.

Methods

Study patients: Twenty-five men with at least 50% luminal diameter obstruction in 1 or more coronary arteries seen angiographically were studied (Table I). Symptom-limited exercise testing was performed according to the Bruce protocol.[12] A 12 lead electrocardiogram modified for exercise testing by Mason et al.[13] and 32 lead body surface maps were obtained at rest in the supine and standing positions, immediately after exercise in the standing position and 1, 3, and 5 minutes after exercise in the supine position. The 12 lead electrocardiogram was also obtained at the end of each 3 minute stage during exercise and at maximal exercise. Each recording from the 12 and 32 lead systems was of 10 seconds' duration. sites were prepared with conductive paste, and after application of both lead sets, the torso was wrapped with 6 inch Ace bandages to reduce motion artifacts. All electrocardiographic comparisons were made using records obtained in the same posture. The 12 lead electrocardiographic response to exercise was interpreted by conventional visual interpretation techniques using 0.1 mV horizontal or downsloping S-T segment depression as a criterion for a "positive" test result.

Body surface map recording and measurements: The system for recording and analyzing the 32 lead body surface maps was developed in our laboratory and was previously described.[14] All 32 leads were simultaneously recorded at 1 ms intervals using signal multiplexing techniques. Each signal was amplified, digitized to 9 bits at 1,000 Hz, and stored on specially formatted flexible disks.

To obtain body surface maps, 5 to 15 P-QRS-T complexes from each of 32 leads were coherently averaged using template matching to reduce muscle noise and respiration-induced baseline shift. Baseline in the averaged complex was established by identifying a sample point in the adjacent P-R intervals at which the signal was "flat."

Torso potential distributions on a 12 × 16 grid (192 points) were estimated from potentials recorded with the 32 lead system. It has previously been demonstrated that such estimates can be made with an average error of only 35 μV RMS and an average correlation of 0.99 with respect to actual recordings from a 12 × 16 electrode grid.[14] Data were displayed as isoarea contour maps of the S-T segment. For the purpose of this study, the S-T segment was characterized as the spatial distribution of the integral of S-T segment voltage over an 80 ms interval beginning with the end of the QRS complex (J point). This "S-T_{80}" isoarea distribution represents the average S-T segment displacement for the 80 ms window. The measurement was appropriate for the purpose of the study, namely, to determine whether particular leads showed S-T segment displacement. It defines the presence of S-T segment displacement but is less sensitive to the shape of the segment than are measurements at a particular instant or a measurement of maximal displacement. Because S-T segment shape has established value in the detection of coronary artery disease, the S-T_{80} measurement is not necessarily optimal for evaluation of that disease. Definition of the most useful features of S-T segment displacement and other electrocardiographic findings in body surface maps associated with exercise testing will require studies of different design than that reported herein.

Body surface S-T_{80} isoarea maps were plotted on the format illustrated in Figure 1. The rectangle represents the thorax displayed as an unrolled cylinder. Location of the mid-axillary and mid-sternal lines is shown on the diagram. The upper margin of the rectangle represents a level just below the jugular notch and the lower margin a level just above the umbilicus. The right and left margins represent the paravertebral lines. The intersections on the grid represent 192 sites on the torso from which electrocardiographic signals are either directly measured or derived. Small dots are sites of actual electrocardiographic measurements using the 32 lead array. Three large dots indicate the locations of the standard V_4–V_6 electrodes. The numbering of rows and columns is indicated to the left of and below the grid. Dotted lines subdivide the body surface into 12 regions labeled A through L.

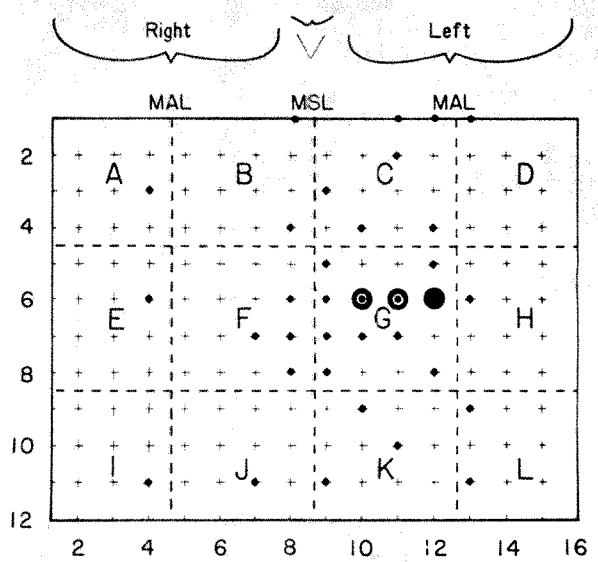

FIGURE 1. Format for plotting body surface maps. The **rows and columns** indicate the locations of 192 body surface sites from which electrocardiographic signals are either directly measured or derived. **Small dots** are the sites of actual electrocardiographic measurements. **Three large dots** indicate the location of standard V_4–V_6 electrodes. A = right upper back; B = right upper chest; C = left upper chest; D = left upper back; E = right mid-back; F = right mid-chest; G = left mid-chest; H = left mid-back; I = right lower back; J = right lower chest; K = left lower chest; L = left lower back; MAL = mid-anterior line; MSL = mid-sternal line.

Results

Clinical features of patients: Clinical, electrocardiographic, and angiographic data on the 25 patients are summarized in Table I. The mean age of these men was 55 years (±7 years standard deviation). Six patients were receiving propranolol, and 1 was on digoxin at the time of study. Twenty patients had a normal 12 lead electrocardiogram at rest, whereas 4 patients had evidence of old myocardial infarction including Q waves and ST-T wave abnormalities; 1 patient had nonspecific ST-T wave abnormalities.

With the criterion of 0.1 mV horizontal or downsloping S-T segment depression, 19 of the 25 patients (78%) had abnormal 12 lead electrocardiographic responses to exercise. Four patients had a borderline re-

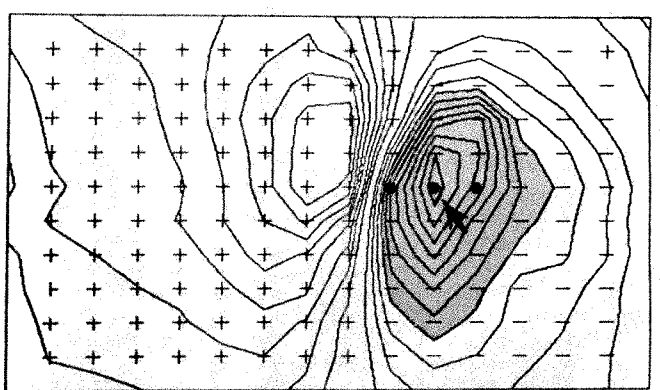

FIGURE 2. Patient 6. S-T_{80} map immediately after exercise. The **arrow** points to the location of the S-T_{80} minimum. The **shaded area** represents the ischemic zone. The **large dots** represent leads V_4–V_6.

* Percentage of total body surface map occupied by this negative area.
† Italicized letter indicates the $S\text{-}T_{80}$ minimum location on the surface map.
AMI = anterior infarct pattern; C = left upper chest; CAD = coronary artery disease; d = digoxin; D = left upper back; ECG = electrocardiogram; G = left mid-chest; H = left mid-back; HR = heart rate; IMI = inferior infarct pattern; K = left lower chest; L = left lower back; LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; LM = left main coronary artery; Meds = medications; N = normal resting electrocardiogram; p = propranolol; RCA = right coronary artery; STT = ST-T wave changes; + = abnormal electrocardiographic response to exercise; − = normal electrocardiographic response to exercise; ± = borderline electrocardiographic response to exercise (0.05–0.1 mV S-T segment depression).

sponse (0.05 to 0.1 mV S-T segment depression), and 2 patients had a normal exercise test. These results are comparable to previously published data on the sensitivity of exercise testing in patients with documented coronary artery disease.

Analysis of $S\text{-}T_{80}$ isoarea maps (Table I): The effects of exercise on the body surface distribution of $S\text{-}T_{80}$ isoarea contours will not be characterized as normal or abnormal because criteria for such classification have not been established. The following descriptors of the $S\text{-}T_{80}$ maps were analyzed to better define the distribution of S-T segment displacement due to myocardial ischemia: (1) the body surface location of the most negative $S\text{-}T_{80}$ area for each patient (defined as the $S\text{-}T_{80}$ minimum); (2) the magnitude of the $S\text{-}T_{80}$ minimum; (3) the size and location of the body surface region(s) represented by $S\text{-}T_{80}$ areas of −8 mV·ms or greater (more negative). This last variable represents the body surface distribution of sites where Wilson terminal electrocardiographic leads would record an average of 0.1 mV or greater S-T segment depression over an 80 ms period.

Eighteen of the 25 patients (72%) developed $S\text{-}T_{80}$ minima more negative than −8 mV·ms and therefore developed zones of S-T segment depression of more than 0.1 mV averaged over 80 ms. These regions of S-T segment depression included the left mid-anterior thorax in all 18 patients. In 9 of them, the $S\text{-}T_{80}$ minimum was located at the conventional V_5 electrode position, and in 3 patients the $S\text{-}T_{80}$ minimum was in close proximity to the V_4 electrode position. In the remaining 6 patients, the $S\text{-}T_{80}$ minimum occurred at body sites other than the standard V_4–V_6 electrode positions. Five of the 6 had $S\text{-}T_{80}$ minima located 1 or more electrode rows inferior to the V_4–V_6 electrode sites; in 1 patient the minimum S-T segment displacement was located 1 electrode row superior to the V_5 chest position. In 5 of the 6 patients, the $S\text{-}T_{80}$ area of −8.00 mV·ms or greater included 1 or more of the V_4–V_6 sites although these sites did not sample the peaks of the distribution.

Of the 7 patients in whom $S\text{-}T_{80}$ minima of −8 mV·ms or greater did not develop, 3 had previous myocardial infarction and were not complaining of angina pectoris at the time of study. The resting $S\text{-}T_{80}$ maps in these 3 patients showed regions of positive $S\text{-}T_{80}$ isoarea contours coinciding with S-T segment elevation on the individual electrocardiographic signals. Too few patients were studied to correlate regions of positive $S\text{-}T_{80}$ areas with angiographic data or location of infarction.

Representative cases: Several examples of patients in whom $S\text{-}T_{80}$ areas of −8.00 mV·ms or greater developed are illustrated in Figures 2 to 4. Figure 2 shows the $S\text{-}T_{80}$ map from the immediate recovery period in Patient 6. The shaded area represents the zone of S-T segment depression averaging at least 0.1 mV or greater. The $S\text{-}T_{80}$ minimum, indicated by

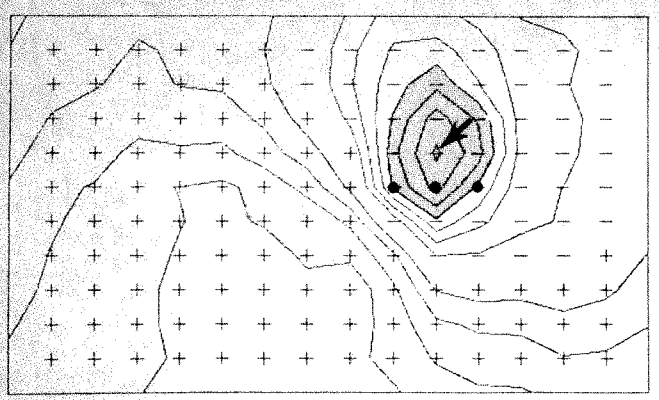

FIGURE 3. Patient 5. S-T_{80} map immediately after exercise. The **arrow** points to the location of the S-T_{80} minimum. The **shaded area** represents the ischemic zone.

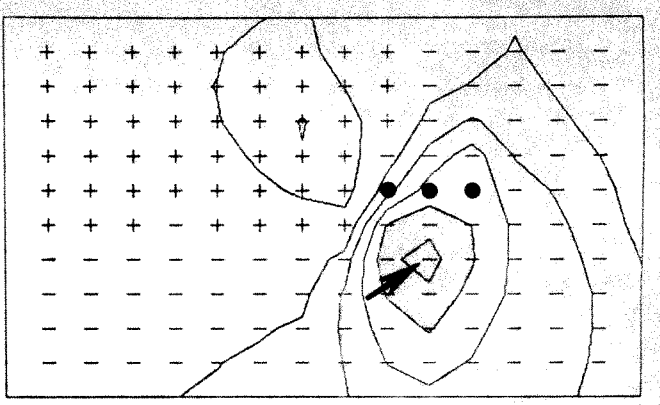

FIGURE 4. Patient 4. S-T_{80} map 1 minute after exercise. The **arrow** indicates the S-T_{80} minimum. The **shaded area** represents the ischemic zone.

the arrow, was −23.49 mV·ms and was located at the standard V_5 electrode site. Coronary angiography revealed an 80% left main coronary stenosis and a 75% stenosis of the 1st diagonal branch.

Figure 3 illustrates the S-T_{80} map of Patient 5. The shaded area again locates the regions on the map where S-T segment depression averaged 0.1 mV or greater. In this patient with a 70% left main coronary stenosis and 75% obstruction of the mid-right coronary artery, the S-T_{80} minimum was located superior to the V_5 chest position (arrow).

In Figure 4 the S-T_{80} map from Patient 4 shows a small shaded zone inferior to the V_4–V_6 chest positions where S-T segment depression averaged 0.1 mV or greater. During this period (1 minute after exercise), the standard electrocardiographic leads did not show significant S-T segment depression. Coronary angiography revealed complete occlusion of the right coronary artery and 50% stenosis of the left anterior descending artery.

Correlation with coronary angiography: The possible relations of coronary artery disease location and severity to body surface distributions of S-T_{80} areas were investigated. In this small group of patients, there was no significant difference in the magnitude of the S-T_{80} minimum or apparent difference in the extent of S-T_{80} negative areas in patients with single as compared with multiple vessel disease. In patients with single vessel disease, there was suggestive but not conclusive evidence that the body surface distribution of S-T segment depression was related to the diseased vessel. Patients with isolated right or left circumflex coronary artery lesions (Cases 4, 8, and 15) had negative S-T_{80} areas in the left lower part of the chest (region K). The location of the S-T_{80} minimum was 2 electrode rows inferior to the V_5 electrode site in 2 of these patients (Cases 4 and 8). In the 3 patients with isolated left anterior descending coronary disease who had S-T_{80} areas more negative than 0.8 mV·ms (Cases 10, 23, and 25), the S-T_{80} minimum was located on the V_5 chest position in all 3 patients.

Discussion

A variety of electrocardiographic lead systems have been evaluated in the exercise laboratory in an attempt to find an optimal set for quantitating the ischemic response to exercise in patients with coronary artery disease. The regional and localized nature of myocardial ischemia precludes any simple lead arrangement that is ideal for all patients. The classic study of Blackburn et al.[8] concluded that the most sensitive single electrode position was the V_5 chest location. Nevertheless, in approximately 10% of their patients the ischemic response was confined to leads with an infero-superior orientation. Most exercise laboratories now use multiple leads to maximize the probability of detecting ischemic electrocardiographic abnormalities in all patients with significant coronary artery disease.

In addition to diagnosing the presence or absence of myocardial ischemia in patients undergoing exercise testing, an ideal electrocardiographic lead system should enable a more quantitative description of the size and location of ischemic myocardial lesions. This information would likely have important clinical implications in patients undergoing exercise evaluations.

Considerable evidence that electrocardiographic examination can be improved by extensive lead sampling has been reported. Clinical studies provide evidence of improved recognition of right ventricular hypertrophy,[15] cardiomyopathy,[16] myocardial infarction,[17] and the location of anomalous atrioventricular conduction pathways.[18] The application of mapping techniques to exercise testing was only recently investigated. The published reports are mainly concerned with methodologic considerations and focus primarily on normal subjects.[10,11]

Role of exercise testing using body surface mapping: Our study suggests that potentially useful electrocardiographic information may be obtained from patients with coronary artery disease during exercise testing using body surface mapping. Of patients with independently documented coronary disease 25% had maximal depression of S-T segment area at sites other than those usually employed in exercise testing. Even though S-T segment area depression was present at the usual sampling sites in most of these patients, the finding that these sites did not sample the maximal depression suggests that improved sensitivity of exercise testing for coronary disease may be possible using body

surface mapping. These findings are compatible with those of Fox et al.[9] in which 13 patients with angiographically proved coronary disease and normal 12 lead exercise tests had S-T segment depression associated with exercise at some sites on a 16 lead precordial grid.

Our study was not extensive enough to adequately evaluate the possibility that body surface mapping may be useful in differentiating the site or defining the severity of coronary artery disease. Some suggestive evidence concerning disease site was obtained, however. All patients with isolated right coronary or left circumflex coronary artery disease had $S\text{-}T_{80}$ minima located on the left lower part of the chest. The study included only 3 patients with an isolated left anterior descending coronary lesion, but in 2 of these the $S\text{-}T_{80}$ minima were not located on the left lower chest. No significant difference was found between patients with single and those with multivessel disease in the magnitude of maximal $S\text{-}T_{80}$ depression or size of the $S\text{-}T_{80}$ area depression of more than 8 mV·ms. However, the possibilities of predicting both location and severity of coronary artery disease by means of body surface mapping should be further evaluated with large numbers of patients and with electrocardiographic variables in addition to the $S\text{-}T_{80}$ area employed in this study.

The S-T segment displacement averaged over 80 ms as measured in this study is not necessarily or even likely to be the most useful electrocardiographic marker of myocardial ischemia. It was considered appropriate for the purpose of this study, which was to determine whether body surface mapping furnished information about the presence and degree of S-T segment displacement that was not evident in the 12 lead examination. Definition of optimal measurements of body surface maps for the detection as well as possible definition of site and severity of coronary artery disease will require additional studies. Such optimal variables will likely include S-T segment slope and magnitude at 80 ms after the J-point.

Conclusion: Body surface mapping after exercise showed that maximal depression of the S-T segment occurred at sites not usually sampled in one fourth of patients with arteriographically proved coronary artery disease. This finding suggests that increased sensitivity of exercise testing may be possible with body surface mapping. Suggestive evidence that body surface mapping may be helpful in defining the location of single vessel disease was also obtained. This possibility and that of estimating the severity of coronary artery disease by body surface mapping with exercise needs further study with larger numbers of patients and electrocardiographic measurements in addition to the one employed in this study.

Scintigraphic Prediction of Pulmonary Arterial Systolic Pressure by Regional Right Ventricular Ejection Fraction During the Second Half of Systole

BRUCE J. FRIEDMAN, MD and B. LEONARD HOLMAN, MD

In 49 patients in whom gated equilibrium ventriculography and cardiac catheterization were performed within a 6 day interval, total and fractional portions of global and regional right ventricular ejection fraction (RVEF) were correlated with pulmonary arterial systolic pressure. Pulmonary arterial systolic pressure was normal (30 mm Hg or less) in 27 patients (Group I) and elevated (31 mm Hg or greater) in 22 patients (Group II). The second-half regional RVEF was 38 ± 8% (mean ± standard deviation) with a range of 30 to 54% for Group I and 22 ± 6% with a range of 13 to 32% for Group II. The difference between the means was statistically significant ($p < 0.001$). Use of a second-half regional RVEF of 30% as the criterion of elevated pulmonary arterial systolic pressure resulted in a sensitivity of 0.86 and a specificity of 1.00. A power curve fit in which pulmonary arterial systolic pressure = 10.91 (second-half regional RVEF)$^{-0.87}$ allowed accurate estimation ($r = -0.85$) of pulmonary arterial systolic pressure from the second-half regional RVEF. It is concluded that second-half regional RVEF may be used to accurately detect pulmonary arterial hypertension and to estimate its extent.

Gated equilibrium ventriculography provides a noninvasive technique for the evaluation of both left and right ventricular (RV) function and wall motion.[1-6] Several investigators[3,6] have used regional changes in count rate to assess quantitatively regional left ventricular (LV) wall motion. In this study we used this approach to assess quantitatively regional (free wall) RV wall motion. The free wall is of special interest because the major contractile motion involved in RV systolic performance is the inward motion of the free wall toward the interventricular septum.[7] We compared various portions of regional and global RV ejection with pulmonary arterial systolic, diastolic and mean pressures, RV systolic pressure, and pulmonary vascular resistance.

Methods

Patient group: The study group consisted of 49 patients from the Brigham and Women's Hospital who had undergone gated equilibrium ventriculography and cardiac catheterization performed within 6 days of each other (1.8 ± 1.6 days, mean ± standard deviation [SD]). Twenty-nine patients who had undergone both studies within 6 days were excluded because of atrial fibrillation (n = 11), clinically evident tricuspid regurgitation (n = 4), and discontinuities in the RV free wall (n = 14). The RV wall was identified from the ejection fraction image.[8] Discontinuities in the RV free wall were defined as regions with an ejection fraction less than 50% occurring within the RV free wall region of interest and involving the full thickness of the free wall. Reasons for discontinuities in the RV free wall included old RV infarction and technical factors such as right atrial interference due to incomplete separation of the right atrium and right ventricle.

There were 35 men and 14 women whose average age was 54 years (range 20 to 78). Their clinical diagnoses are listed in Table I. A majority of the patients had coronary heart disease defined on cardiac catheterization as greater than 50% luminal narrowing of at least 1 major coronary arterial branch. Five patients had previous cardiac surgery including coronary

arterial bypass grafting in 2 patients, and repair of an atrial septal defect, aortic valve replacement, and mitral valve replacement in 1 patient each.

Cardiac catheterization: Each patient underwent right and retrograde left heart catheterization, including left ventriculography, and 40 patients had coronary arteriography. Patients were premedicated with diazepam, 5 to 10 mg orally, and diphenhydramine, 25 to 50 mg orally. With the patient supine and in the resting state, systemic arterial, LV, pulmonary capillary wedge, pulmonary arterial, RV, and right atrial pressures were measured using fluid-filled catheters which were calibrated with the mid-chest as the baseline. Pulmonary and systemic blood flows and resistances were calculated by the Fick principle on the basis of measured oxygen consumption. In 1 patient with an atrial septal defect and 1 patient with chronic pulmonary disease, pulmonary arterial pressures were obtained before and after the inhalation of oxygen.

The patients were classified into 2 groups. Twenty-seven patients (Group I) had normal pulmonary arterial systolic pressure (30 mm Hg or less) and 22 patients (Group II) had elevated pulmonary arterial systolic pressure (greater than 30 mm Hg).

Radionuclide data acquisition: In vivo red blood cell labeling was performed by the intravenous injection of 5 mg of unlabeled stannous pyrophosphate (Pyrolite, New England Nuclear) followed in 15 to 20 minutes by approximately 25 mCi of technetium-99m pertechnetate.[9] The studies were obtained with a portable Anger scintillation camera with a high sensitivity, 30° slant hole collimator (Engineering Dynamics, Lowell, Massachusetts), as previously described.[8,10] The patient was positioned in the modified left anterior oblique position with the long axis of the left ventricle aligned vertically, and the obliquity adjusted to provide the greatest separation of the right and left ventricles.[3,8] The use of this position has been validated for global RVEF; left or right atrial interference was minimized because of the 30° caudal tilt.[11]

After equilibration of the radionuclide in the intravascular space (about 5 to 10 minutes), gated (25 ms) images were collected and stored in frame mode on a digital computer (PDP 11/34, Digital Equipment). Only cycles within a cardiac cycle length tolerance of ±50 ms were processed.

The 2 patients who had pulmonary arterial pressure measured with and without oxygen also had gated equilibrium studies performed before and during the inhalation of oxygen.

Data processing: Global and regional LV function were assessed quantitatively and an ejection fraction image was obtained by methods previously described.[8] With use of the ejection fraction image, a region-of-interest was placed around the RV free wall, including all pixels greater in intensity than the mid-point of a 16-shade value scale and thus greater than 50% of corrected end-diastolic counts, avoiding the right atrium and including the apex of the right ventricle (Fig. 1). The medial border of the RV free wall region-of-interest in the apical region was extended to within 1 to 3 pixels of a line extended downward from the most medial point of the septal portion of the LV region-of-interest. A para-RV background region-of-interest 1 to 2 pixels lateral to the outer border of the RV free wall region-of-interest and 3 to 4 pixels in width, extending the full length of the free wall region-of-interest, was also drawn (Fig. 1).

The RV free wall region-of-interest time-activity curve was then printed. The RV end-diastolic frame (50 ms frame with the largest number of counts just before ejection), end-systolic frame (50 ms frame with the lowest number of counts at the end of ejection), mid-systolic, one-third systolic and two-thirds systolic frame (50 ms frame at one half, one third, and two thirds of RV systole) were selected. To improve the statistical reliability of the data, each 50 ms frame was derived by adding 2 adjacent 25 ms images. Background correction was made by dividing the number of counts in the para-RV background region-of-interest at end-diastole (50 ms frame) by the number of pixels in the para-RV background region-of-interest, thus normalizing the background per pixel. The product of the para-RV background per pixel and the number of pixels in the RV free wall region-of-interest were subtracted from the RV free wall region-of-interest end-diastolic counts to obtain the background-corrected end-diastolic counts.

The second half, last third, and total regional RVEF were defined by subtracting the counts in the end-systolic frame from the counts in the mid-systolic, two-thirds systolic, and end-diastolic frames, respectively, and dividing the differences by the background-corrected end-diastolic counts. The middle-third regional RVEF was defined by subtracting the counts in the one-third systolic frame from counts in the two-thirds systolic frame and dividing the difference by the background-corrected end-diastolic counts.

Global RVEF was determined in representative patients, 22 from Group I and 15 from Group II, using a computer-selected background and a single region-of-interest excluding the infundibulum. The second-half global RVEF was also determined in 9 representative patients from Group I and 9 patients from Group II with the same regions-of-interest used for calculating global RVEF. The second-half global RVEF was defined in the same manner as the second- half regional RVEF except that global- and computer-selected background regions-of-interest were substituted for the RV free wall and para-RV background regions-of-interest.

Reproducibility was evaluated in 7 patients who had undergone repeated gated equilibrium studies several hours apart. Studies were performed after repositioning both the patient and the scintillation camera but without significant change in the patient's clinical status. In each case, the left,

* PASP = Mean pulmonary arterial systolic pressure ± SD (mm Hg). The mean PASP ± SD for each of the representative subgroups of Groups I and II used in the comparison of global RVEF is shown above their respective ejection fractions.

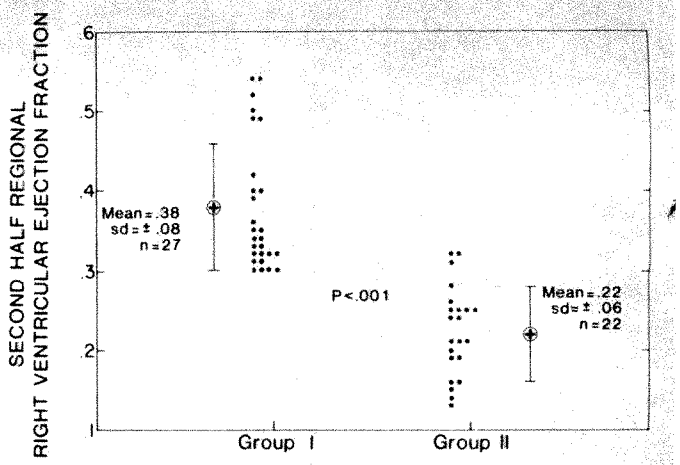

FIGURE 2. Comparison of second-half regional RVEF in patients with normal (30 mm Hg or less, Group I) and elevated (greater than 30 mm Hg, Group II) pulmonary arterial (PA) systolic pressure. Note that the second-half RVEF was significantly lower in the patients with elevated pulmonary arterial systolic pressure.

right, and background regions-of-interest were drawn independently.

To determine the interobserver error, 10 studies were randomly selected and analyzed independently by 2 observers. To determine the intraobserver variability, 10 studies were analyzed by 1 observer on separate occasions at least 6 months apart.

Radionuclide-hemodynamic comparison: To determine the utility of the various radionuclide methods in detecting patients with abnormal pulmonary arterial systolic pressure, a modified 2-sample *t* test was used to compare Groups I and II. Any p value less than 0.05 was considered significant. After examination of the data, the correlation between pulmonary arterial systolic pressure and global as well as regional RVEF was assessed using linear, logarithmic, and power fits. The correlation between second-half regional RVEF and pulmonary arterial diastolic and mean pressures, RV systolic pressure, and pulmonary vascular resistance was also assessed with linear, logarithmic, and power fits.

Results

Second-half regional RVEF: The second-half regional RVEF for Group I (normal pulmonary arterial pressure) was 38 ± 8% (mean ± SD), with a range of 30 to 54%. The second-half regional RVEF for Group II (elevated pulmonary arterial pressure) was 22 ± 6%, with a range of 13 to 32%. The difference between the means was statistically significant (p <0.001). When we used a second-half regional RVEF less than 30% as the criterion of elevated pulmonary arterial systolic pressure, the result was a sensitivity of 0.86 and a specificity of 1.0 for separation of patients with normal and elevated pulmonary arterial systolic pressure.

There was no significant difference between Groups I and II when total or second-half global RVEF was used (Table II). However, there were significant differences between the 2 groups when regional RVEF was used. The use of second-half regional RVEF resulted in the best separation of the 2 groups (Fig. 2).

Predicting elevated pulmonary arterial pressure from second-half regional ejection fraction: Preliminary examination of data showed a nonlinear relation of second-half regional RVEF and pulmonary arterial systolic pressure. A power curve fit with a pulmonary arterial systolic pressure of 10.91 (second-half regional RVEF)$^{-0.87}$ allowed estimation of pulmonary arterial systolic pressure ($r = -0.85$) (Fig. 3). The logarithmic fit also appeared to accurately predict pulmonary arterial systolic pressure ($r = -0.84$). There was some clustering of points in the 20 to 28% range of second-half regional RVEF with pulmonary arterial sys-

TABLE III Correlation Using Linear, Logarithmic, and Power Fits of Pulmonary Arterial Systolic Pressure With Fractional and Total, Regional, and Global RVEF

	Type of Fit

TABLE IV Comparison of Second-Half Regional RVEF with Pulmonary Mean Pressure, Pulmonary Diastolic Pressure, Right Ventricular Systolic Pressure, and Pulmonary Vascular Resistance

	Type of Fit		
	Linear	Logarithmic	Power
Pulmonary arterial mean pressure	−0.76	−0.81	−0.72
Pulmonary arterial diastolic pressure	−0.73	−0.79	−0.78
RV systolic pressure	−0.73	−0.74	−0.81
Pulmonary vascular resistance	−0.44	−0.44	−0.47

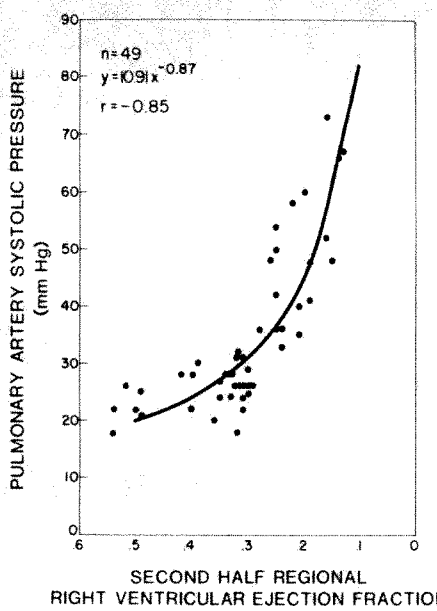

FIGURE 3. Correlation between pulmonary arterial systolic pressure and second-half RVEF.

tolic pressure of 32 to 60 mm Hg. Correlations of pulmonary arterial systolic pressure with total global, second-half global, total regional, second-half regional, middle-third regional, and last-third regional RVEF are shown in Table III. The correlation of second-half regional RVEF with pulmonary mean pressure, pulmonary arterial diastolic pressure, RV systolic pressure, and pulmonary vascular resistance are shown in Table IV. The best correlation obtained was between second-half regional RVEF and pulmonary arterial systolic pressure.

Effect of oxygen therapy: Two patients treated with oxygen both demonstrated a decrease in pulmonary arterial systolic pressure and an increase in second-half regional RVEF during oxygen therapy (Table V). Although the directional change in second-half regional RVEF was appropriate, the change was greater than would be expected from the decrease in pulmonary arterial systolic pressure alone after inhalation of oxygen during cardiac catheterization.

Reproducibility: The intra- and interobserver errors were low. Correlation between the second-half regional RVEF obtained by the same observer was good (r = 0.85), with a standard error of the estimate of the second measurement given the first of 0.06. The absolute mean difference between the 2 measurements was 0.01. Correlation between the 2 observers was good (r = 0.77), with a standard error of the estimate of 0.08. The absolute mean difference between the 2 observers was 0.04.

Correlation was also good between the results of the first and second run in patients having 2 independent studies (r = 0.77). The standard error of the estimate of the second measurement given the first was 0.04, and the absolute mean difference between the 2 measurements was 0.01.

TABLE V Summary of Studies in Patients Before and After the Inhalation of Oxygen*

	Patient 1		Patient 2	
	Off Oxygen	On Oxygen	Off Oxygen	On Oxygen
Pulmonary arterial systolic pressure (mm Hg)	60	46	63	58
Pulmonary vascular resistance (dynes-s-cm^{-5})	394	. . .	509	426
Second-half regional RVEF (%)	20	42	22	33
Global RVEF (%)	48	45	33	32

* Patient 1 had chronic obstructive lung disease and was studied before and during the administration of 32% oxygen; Patient 2 had an atrial septal defect and was studied before and during the administration of 100% oxygen.

Discussion

Use of regional RV function: The complex geometric shape of the right ventricle has been a major impediment to the study of RV volume and function. Assessment of global RV function from gated equilibrium studies has been hindered by activity emanating from adjacent structures such as the right atrium and left ventricle. The modified left anterior oblique view[10] provides an opportunity to isolate the free wall of the right ventricle and to study the ejection of blood resulting from the movement of the free wall toward the septum without right atrial or left ventricular interference.

Although the importance of the RV free wall has been questioned,[12–14] recent studies suggest that it is especially important in RV contraction[7,15–17] and have shown its increased prominence in patients with pulmonary hypertension.[18–21] Rushmer[7] postulated that the geometric configuration of the right ventricle is very important in the afterload dependence of this chamber. The right ventricle surface area is large in comparison with its volume. Normally the right ventricle ejects blood by a uniform reduction in the RV free wall-to-septal distance and in its free wall surface area.[7] This inward motion of the RV free wall toward the septum is the major contractile movement of the right ventricle.[7,15] Santamore et al.[15] established the importance of the septal-to-free wall shortening and contraction in the transverse direction of the sinus and conus regions. They found that increasing pulmonary arterial pressure in closed-chest, anesthetized, paced dogs with implanted radiopaque markers led to an increase in RV end-diastolic length, an increase in RV pressures, and reductions in cardiac output, percent shortening, and time to maximal velocity of shortening. Although the greatest increases in end-diastolic length occurred in RV free wall-to-septal motion, this increase was not significantly different from that observed in the other dimensions. In addition, although the time to maximal velocity of shortening appeared most markedly prolonged in the septal-to-free wall dimension, this change

was not significant. Other factors that may have contributed to the better correlation between pulmonary arterial systolic pressure compared with regional rather than global RV contraction may be overlap of the right atrium in the region of the conus and passive movement of the pulmonary outflow tract during the cardiac cycle. We also chose to eliminate the portion of the RV apex adjacent to the left ventricle which, although highly contractile, may have included overlap from the left ventricle.

RV systole is characterized by a sequential contraction beginning at the inflow tract and extending into the conal region.[15,22] These 2 embryologically and anatomically different areas can develop markedly different intracavitary pressures during various interventions.[22,23] Whereas a marked intraventricular pressure gradient is measured from sinus to conus, there is a relatively small gradient from conus to pulmonary artery. Thus the infundibular region of the right ventricle may add little to pressure or force generation and may act more as a pressure regulator protecting the pulmonary vasculature.[22] These findings functionally characterize the RV free wall and may partly explain the observed correlation of pulmonary arterial systolic pressure with regional (free wall) but not global RVEF.

RV ejection and systolic pulmonary arterial response: Several studies[24–27] have suggested that RV performance as measured by the RVEF may be closely related to afterload. An important component of RV afterload is pulmonary arterial systolic pressure. Studies[26] have attempted to characterize the relation between global RVEF and pulmonary arterial pressure. Our global as well as total regional RVEF showed some correlation with pulmonary arterial systolic pressure. The best correlation ($r = -0.85$) was found between second-half regional RVEF and pulmonary arterial systolic pressure.

Experimental data support our findings. Simultaneous pressure measurements in the right ventricle and pulmonary artery using high fidelity catheters (Fig. 4) have shown that in early to mid-systole there is a physiologic gradient across the pulmonary valve. This early systolic difference between RV and pulmonary arterial pressure has been termed the *ventricular impulse*.[28] Okino and Spencer[29] reported that in the first 30 to 40% of RV systole, RV pressure exceeds pulmonary arterial pressure and pulmonary arterial flow is accelerated. During the last 60 to 70% of RV systole, RV pressure is less than pulmonary arterial pressure and pulmonary arterial flow decelerates. Dorethy et al.[28] reported the positive RV impulse time in man to be 178 ± 50 ms and the ratio of RV impulse time to right ventricular ejection time to be 0.50 ± 0.13.

It has been shown[30] in isolated canine hearts that the instantaneous relation of RV pressure to volume is as linear as that found in the left ventricle over a wide physiologic range. A striking difference between the ventricles was found in the shape of the pressure-volume loops for ejecting beats. LV pressure-volume loops are nearly rectangular. RV loops are more triangular in shape, with ejection continuing well past peak pressure.[30]

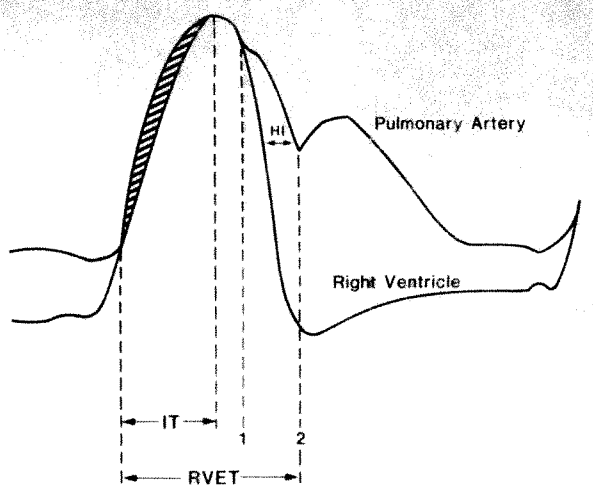

FIGURE 4. Adapted drawing of simultaneous pulmonary artery and RV pressure tracings.[27,29,30,32] The impulse time (IT) is the period of time RV pressure exceeds pulmonary arterial pressure. The **hatched area** represents the positive impulse gradient when acceleration of blood occurs. The hangout interval (HI) is the interval separating the RV pressure curve and the pulmonary incisura.[2] In the later part of systole between point 1 (pressure crossover) and point 2 (pulmonary valve closure), RV pressure is less than pulmonary arterial pressure.

The low resistance and high compliance of the normal pulmonary vasculature are largely responsible for the early peaking of RV pressure and its gradual decline.[30–33] Murgo et al.[32] suggested that inertia is the major component opposing flow or governing the pressure-flow relation across the pulmonary valve in early systole; other factors as resistance and altered compliance become more important later in systole. When pulmonary hypertension results, RV and pulmonary arterial peak pressure occur later in systole with obliteration of the RV pulmonary arterial pressure gradient.[31,32] Patients with pulmonary hypertension also have a marked reduction in the hangout interval,[31,34] the time interval separating the incisura of the pulmonary arterial curve from the RV tracing (Fig. 4). In normal subjects this interval is the last 30 to 90 ms of RV systole.[31]

Clinical utility: A noninvasive predictor of pulmonary arterial hypertension would be helpful in the evaluation and follow-up of acquired as well as congenital heart disease. Measurement of second-half regional RV ejection fraction appears to accurately discriminate normal from elevated pulmonary arterial pressure in the patient group we studied.

We chose not to study patients with atrial fibrillation because of the nonuniformity of their cardiac cycles. Patients with tricuspid regurgitation or RV failure and secondary tricuspid regurgitation were excluded because regurgitation provides a low pressure outlet into the right atrium. Adults with RV outflow obstruction or other right-sided valvular lesions and children were not found in the group available for evaluation. The population studied did include 6 patients with RV volume overload.

Another requirement in this study was that there be an intact RV free wall ejection shell without RV asynergy. This criterion eliminated patients with RV infarction who have had sufficient RV damage to alter contraction and, hence, RVEF. RV asynergy was not commonly seen, even with severe right coronary arterial lesions.[24,35,36] This was evidenced by the inclusion in this study of 4 patients with complete occlusion and 2 patients with 99% stenosis of the right coronary artery.

Implications: A radionuclide technique was used to assess the fractional ejection of blood from the region of the RV free wall during the second half of RV systole. This method detects pulmonary arterial hypertension accurately. However, its application as a quantitative index of pulmonary arterial pressure should be treated more cautiously. Although there is a good correlation between pulmonary arterial pressure and regional RVEF during the second half of systole, small changes in ejection fraction reflect large changes in pressure in the abnormal range. Furthermore, the reproducibility studies suggest that a high degree of technical proficiency is required to apply this method accurately as a quantitative index.

Effect of Beam Directional Alterations on Left Ventricular Shortening Fraction

HEINZ R. HOENECKE, Jr., STANLEY J. GOLDBERG, MD, DAVID J. SAHN, MD, HUGH D. ALLEN, MD, and LILLIAM M. VALDES-CRUZ, MD

In this study, the dependence on beam direction of the echocardiographically derived fractional shortening of the left ventricular minor axis was evaluated. A directionally oriented, steerable cursor was used to select M-mode lines from a 2-dimensional image at the chordal level. Seven M-mode traces were derived from each image, 1 along the true ventricular meridian and 3 at known deviations on either side of the meridian. M-mode traces, thus derived, all appeared acceptable for measuring wall or cavity dimensions. Results indicate a progressive increase in shortening fraction ($p < 0.05$) for deviations more than 25% of the distance between the meridian and the lateral or medial papillary muscle heads. Decreases in left ventricular dimensions in diastole and systole with progressive deviation from the meridian accounted for the decrease in shortening fraction. Spatial orientation is required for reproducible shortening fraction measurements.

Left ventricular shortening fraction determined with M-mode echocardiography is frequently used as an important indicator of cardiac function.[1-3] Sensitivity and reproducibility of the measurement is generally accepted but not rigorously proved.

Measurements of the left ventricular cavity used to calculate this ratio are usually obtained from M-mode echocardiograms obtained at the chordal level. Proper orientation of the M-mode beam with respect to the long axis of the left ventricle is usually assumed to be standard because chordae tendineae, septum, and the left ventricular posterior wall are imaged simultaneously. This orientation is supposed to provide a minor axis determination.[4] Often, the area providing the best posterior wall recording is considered to be the optimal chord because reflections are thought to return in greatest amplitude from the most perpendicular surface.[5] A minor axis may also be approximated by scanning the left ventricle in a direction perpendicular to the long axis (T scanning)[6] and selecting for measurement the echocardiogram with the largest cavity size. The T-scan, although probably useful, is cumbersome and frequently difficult to accomplish. Furthermore, the largest diameter can not always be assumed to be the meridian if the ventricle is distorted or the plane not truly perpendicular to the long axis.

Limitations of localization exist for an M-mode scan. Transection of a circle (such as the left ventricle) by an M-mode beam produces only 2 points that cannot be

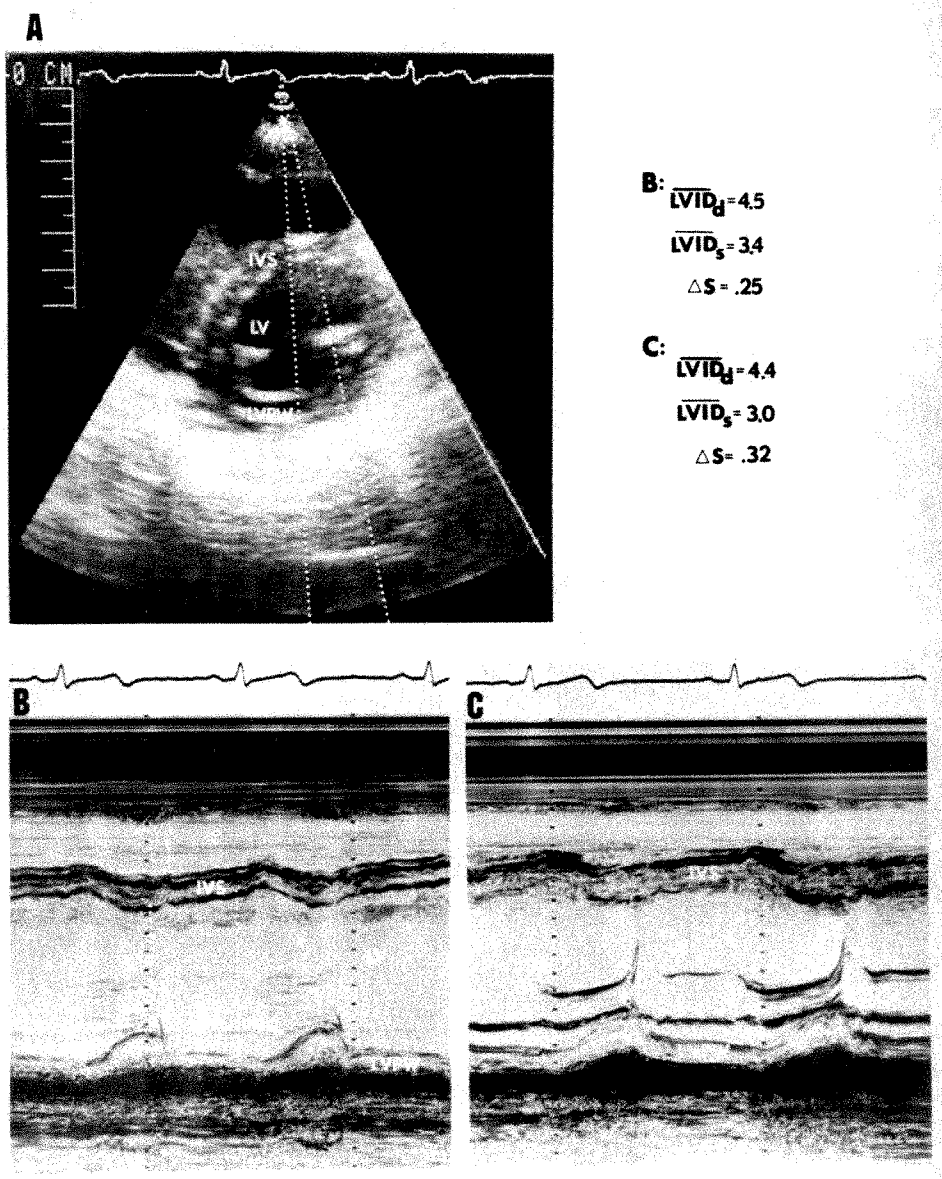

FIGURE 2. Panel A, 2-dimensional short axis image of the left ventricle at the chordal level. The **dotted lines** represent the path of the M-mode beam represented in **panels B and C. Panels B and C** are M-mode tracings recorded from the position of lines B and C in **panel A.** These tracings are acceptable for standard measurements; however, note a slight breakup in the septal endocardium in **panel C.** This may or may not suggest **panel B** is preferable for measurement. Note the change in shortening fraction. The **bottom of the first white dot** is at the leading edge of the septal endocardium. Abbreviation as in Figure 1.

immediately spatially oriented with respect to the true diameter. Also, ultrasonic beams have definite width that causes structural overlap.[7] Clearly, left ventricular cavity dimensions and shortening fraction calculation are dependent on finding the true minor axis diameter.[8] The possibility of recognizing this true minor axis by M-mode echocardiography was the subject of this investigation.

Methods

The patient group consisted of 14 subjects aged 7 to 25 years. Thirteen subjects had normal findings and 1 had rheumatic aortic insufficiency and mitral insufficiency. We used an Electronics for Medicine/Honeywell echocardiograph which allowed nearly instantaneous switching between the mechanical sector 2-dimensional scan and a spatially oriented M-mode from any selected information line. Hard copy records of cross-sectional and M-mode images were made with a Honeywell LS8 recorder. For each subject, a 2-dimensional short-axis image of the left ventricle at the chordal level was obtained. Great care was taken to be certain that this image was 90° to the long axis and that a circular left ventricular image persisted throughout the cardiac cycle. Circularity reasonably assured a plane orthogonal to the long axis. The M-mode cursor was placed at the minor axis meridian (Fig. 1). A freeze frame of the 2-dimensional image was recorded at end-diastole for orientation and documentation, and an M-mode hard copy was recorded of a number of cardiac cycles representative of the cursor location. Hard copies of successive 2-dimensional freeze frames and M-mode samples were taken after deviating the interrogation M-mode line progressively in 4° increments from the meridian, until an acceptable M-mode tracing could not be obtained. Failure occurred when the cursor intercepted either the medial or lateral papillary muscle area in the scan plane just inferior to the chordal level. An acceptable M-mode tracing was defined as successful imaging of chordal structures, both endocardial surfaces of the septum, and endocardial and epicardial surfaces of the left ventricular posterior wall. The appearance of echoes beyond maximal deviation was one of papillary imaging and one of multiple echoes of both septal and posterior endocardial walls

without clear delineation of either structure. Maximal deviation in the right and left direction was defined as full or 100% of the possible geometric deviation. Because angular measurements of the deviation required to lose an acceptable M-mode differed among subjects, the selected M-mode lines from all subjects were normalized with respect to the amount of deviation before imaging papillary muscle landmarks. Lines of interrogation were defined as 0% deviation (meridian), and within the first (20 to 25%), second (26 to 50%), third (51 to 75%), or fourth (76 to 100%) quartile of the available deviation from the meridian. Each quartile represented approximately a 4° successive deviation beginning at the meridian.

Measurements of each M-mode echocardiogram were made according to leading edge methodology, and we also adhered to the other recommendations of the American Society of Echocardiography.[4] Specifically, left ventricular internal dimension in diastole (LVIDd) was measured at the first deflection of the QRS complex. Left ventricular internal dimension in systole (LVIDs) was measured at the point of maximal posterior excursion of the septum. The shortening fraction (ΔS) of each acceptable M-mode echocardiogram was calculated according to the following equation: ΔS = (LVIDd − LVIDs)/LVIDd.[2]

Meridional values of LVIDd, LVIDs, and ΔS were compared by the t test with similarly measured values of chords from the same subject taken from information lines off the meridian.

Results

Eleven of 14 subjects had acceptable images in which septal and left ventricular posterior wall endocardial surfaces could be clearly identified on 2-dimensional and M-mode echocardiographic records. The cursor could be deviated further from the meridian in some subjects than in others and still record an acceptable M-mode echocardiogram. In a few subjects, the left ventricle was imaged more easily on one side of the meridian than on the other.

An acceptable M-mode echocardiographic image could be obtained from information lines that did not pass through the meridian of the ventricle. Figure 2 shows typical M-mode images from locations along and off the meridian. By generally accepted standards,[4] either trace would be suitable for measuring the ventricular cavity at the chordal level.

Figure 3 shows mean results for the 11 subjects with acceptable echocardiograms. A significant decrease in both LVIDd and LVIDs was found when the beam was deviated greater than 50% of the useful perimeter from the meridian. A significant increase in shortening fraction occurred at greater than 31% deviation. At greater than 50% deviation, the shortening fraction increased a mean of 25% above the value at the meridian.

Discussion

The major finding of this study is that the direction of an M-mode beam through the left ventricle cannot be accurately ascertained by qualitative aspects of the M-mode echocardiogram. Images that would be considered acceptable can be recorded off the meridian. A

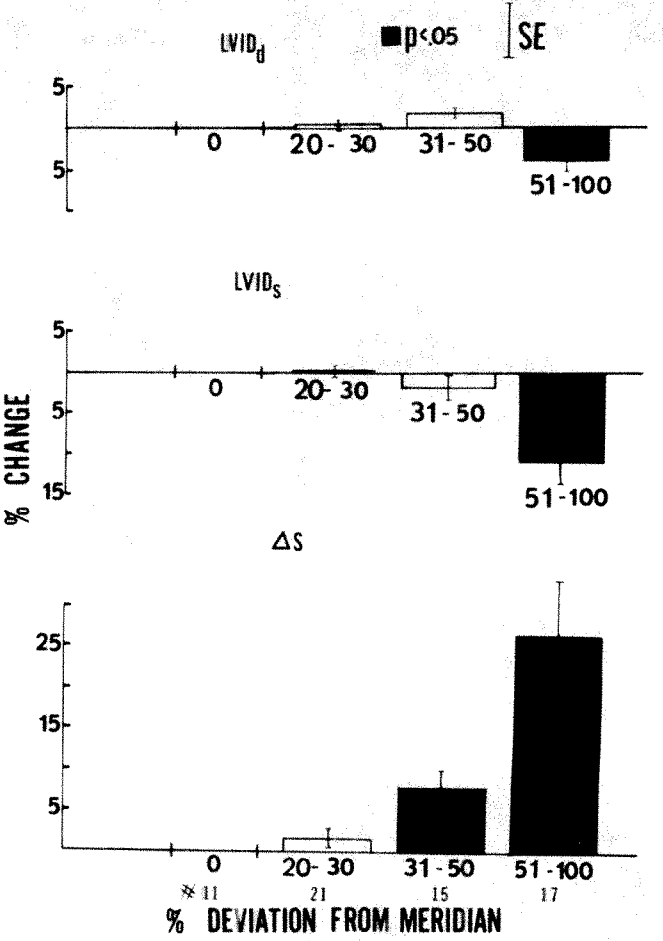

FIGURE 3. Effect on shortening fraction (% change) as the M-mode cursor is deviated from the meridian. The **horizontal axis** shows the percent deviation from the meridian. LVIDd = left ventricular internal dimension in diastole; LVIDs = left ventricular internal dimension in systole; ΔS = shortening fraction; SE = standard error; # = number of measurements.

T scan[6] can be performed to attempt to define the largest dimension in a normally shaped ventricle, but this is time-consuming and difficult in some patients. Further, the assumption that the largest diameter observed on a T scan is the meridian is not necessarily correct, for the transducer may image a plane angled somewhat superiorly or inferiorly from a true short axis. These problems of M-mode echocardiographic orientation can produce significant variation in cavity dimensions and shortening fraction calculations.

The heart as seen on echocardiography with a stationary transducer has cyclic motion in all 3 axes.[9] If the examiner employs extreme care and has awareness of the spatial position shift during the cardiac cycle, it may or may not be possible to track this cardiac motion with 2-dimensional echocardiography so that the same portion of the ventricle is imaged and measured in systole and diastole. Tracking is not possible by M-mode echocardiography alone. M-mode images may detect a

smaller than actual systolic cavity dimension because the ventricle has moved from the diastolic position, even if diastolic size is accurately imaged. The ability to recognize an incorrect image is limited. Although we did not study wall, septal, or right ventricular cavity measurements, our results show a limited ability to be certain that the beam is perpendicular to the structure of interest. Thus, it is possible that these dimensions may also be subject to slant measurement errors.

In summary, this investigation demonstrated that conventional M-mode measurements of left ventricular dimension may be somewhat unreliable because subjectively acceptable, but different, M-mode images may be obtained when the ultrasonic beam is on, or angled off, the true ventricular meridian. Measurements of the left ventricular internal dimension will vary depending on the angle. Accordingly, a derivative of cavity measurements such as shortening fraction or ejection fraction can change as a function of the angle. Also, the dimensional change may be due to the additional problem of locating the same portion of the cavity for measurement in systole and diastole. These problems reduce the usefulness of M-mode measurements, especially those which depend on subtracting systolic dimension from diastolic dimension. This investigation suggests that M-mode records derived from 2-dimensional images or measurements on the 2-dimensional image provide more assurance that a measured dimension represents the actual value.

Low Energy Countershock Using an Intravascular Catheter In an Acute Cardiac Care Setting

RAYMOND YEE, MD, DOUGLAS P. ZIPES, MD, SAJAD GULAMHUSEIN, MD, MICHAEL J. KALLOK, PhD, and GEORGE J. KLEIN, MD

We examined the feasibility, effectiveness, and safety of using an intravascular catheter positioned in the right ventricular apex for countershock in a coronary care unit setting in 8 patients who had recurrent ventricular tachyarrhythmia. Countershock using 2.5 to 40 J stored energy (damped sinusoidal wave form) was attempted 115 times to terminate 100 episodes of ventricular tachyarrhythmia (ventricular tachycardia, 91; ventricular flutter, 3; ventricular fibrillation, 6). Eighty-six (87%) of 99 countershock attempts for ventricular tachycardia, 3 (60%) of 5 for ventricular flutter, and 4 (36%) of 11 for ventricular fibrillation were successful using this technique. The catheters remained in stable position for 1 to 16 days without dislodgment. A majority of the countershocks were delivered by the regular nursing staff in the coronary unit.

We conclude that low energy countershock through an intravascular catheter system is feasible, safe, and effective in a coronary care unit setting. Such a system should be beneficial in the acute management of patients who have recurrent ventricular tachycardia or fibrillation. The catheter lead may also prove useful in managing ventricular tachyarrhythmias that occur during electrophysiologic studies.

Patients with unstable cardiac disease may experience frequently recurring ventricular arrhythmias requiring repeated external countershock while appropriate medical management is being instituted. Repetitive countershocks can be psychologically and physically traumatic for these patients and may be associated with a risk of further myocardial necrosis.[1] The pressure on the medical staff to control arrhythmias quickly under these circumstances may result in the overzealous use of antiarrhythmic agents with increased risk of drug toxicity.

We studied the feasibility, effectiveness, and safety of using an intravascular catheter lead system to help control arrhythmias in 8 patients referred for management of frequently recurring, sustained ventricular tachyarrhythmia. In particular, we assessed the usefulness of this catheter system for overdrive termination of ventricular tachycardia, low energy cardioversion, and defibrillation and temporary pacing in the event of bradycardia.

From the Department of Medicine, Division of Cardiology, University Hospital, London, Ontario. This study was supported in part by funds from the Ontario Heart Foundation, Toronto, Ontario, Canada. Manuscript received February 22, 1982; revised manuscript received April 19, 1982, accepted April 26, 1982.

Methods

Patients: All patients were referred to the Coronary Care Unit at University Hospital for the management of recurrent ventricular tachycardia or fibrillation requiring 1 to 20 external countershocks before transfer (Table I). Prior approval for the use of the countershock catheter in such patients was obtained from the Ethics Committee at The University of Western Ontario. Written, informed consent was obtained from each patient. All 8 patients were men, aged 35 to 63 years. Six patients had coronary heart disease (2 with acute myocardial infarction) and 2 patients had cardiomyopathy. Six of these 8 patients developed ventricular arrhythmia requiring countershock.

Description of the catheter system: The countershock lead (Medtronic, DFX-2) is a tripolar 9.5Fr, 100 cm polyether urethane catheter (Fig. 1) with a central lumen for guide wire manipulation. The catheter has 4 stainless steel electrode sleeves, each with a surface area of 125 mm^2. The most distal electrode sleeve (A) is located at the catheter tip, and a second

AMI = acute myocardial infarction; CAD = coronary artery disease; CTR = cardiothoracic ratio; External CS = number of transthoracic countershock attempts before insertion of lead; R wave = R-wave amplitude measured from catheter distal electrode; VF = ventricular fibrillation; VFL = ventricular flutter; VT = ventricular tachycardia; VTA = ventricular tachyarrhythmia.

electrode sleeve (B) is located 5 mm proximally. The other 2 sleeves, separated by a distance of 5 mm (C and D), are located 100 mm from sleeve B and constitute a single electrode. Each electrode is connected by a separate conductor coil wire to 1 of 3 connector pins at the proximal end of the catheter. In situ, the distal electrodes (A and B) are positioned in the right ventricular apex and the proximal electrode sleeves (C and D) are located approximately at the junction of the superior vena cava and the right atrium (Fig. 2). The distal poles A and B can be used as a bipolar pacing pair. For defibrillation and cardioversion, electrodes A and B become common (the cathode) and the proximal electrodes (C and D) become the anode.

The catheter was inserted employing a standard percutaneous introducer into the left subclavian vein and advanced using fluoroscopy to the right ventricular apex. After insertion, the amplitude of the R wave recorded from the distal electrodes (A and B) was measured daily as one index of lead dislodgment, using a Medtronic 5300 pacing system analyzer. Lead position was verified every 12 to 24 hours by a chest radiograph (Fig. 2).

The lead was then interfaced to a commercially available Hewlett-Packard 78619A defibrillation unit, which produces a damped sinusoidal discharge wave form, through a switch box and current attenuator constructed in the University Hospital Biomedical Engineering Department. A programmable stimulating device or temporary pacemaker was connected to the distal electrode pair by the switching box.

Protocol: Coronary care unit nurses and house-staff were instructed in the proper operation of the unit before each change of shift. Upon recognition of sustained ventricular tachyarrhythmia, the staff was instructed to deliver shocks in incremental doses until successful reversion to sinus rhythm occurred. Energy levels 2.5, 5.0, 7.5, 10, 15, 20, 30, and 40 J were

* Numerators = number of successful countershock attempts at specified energy dose; denominators = total number of countershock attempts delivered; VF = ventricular fibrillation; VFL = ventricular flutter; VT = ventricular tachycardia.

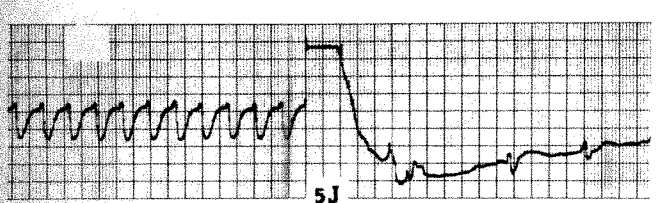

FIGURE 3. Patient 2. Cardioversion using intravascular catheter countershock at 5 J. A lead II monitor strip shows 11 beats of ventricular tachycardia. A synchronized 5 J discharge is delivered, restoring sinus rhythm.

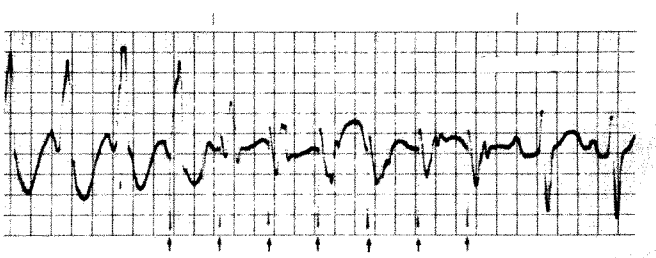

FIGURE 4. Patient 5. Burst ventricular pacing using countershock catheter. Ventricular tachycardia at cycle length 520 ms is entrained by pacing stimuli (**arrows**) at a cycle length of 500 ms. Abrupt termination of pacing results in restoration of sinus rhythm.

chosen and delivered in the synchronized (for ventricular tachycardia and flutter) or nonsynchronized mode (ventricular fibrillation). A second conventional Hewlett-Packard 78619A defibrillator was available for back-up transthoracic shocks.

The initial energy dose selected was 5 J for ventricular tachycardia and flutter, while defibrillation attempts for ventricular fibrillation started at 10 J. After 5 consecutive successful attempts, the coronary care unit staff was instructed to reduce the energy used to the next lower level. However, if any failures occurred, the dose was doubled and not reduced until 5 consecutive successful attempts were attained. While every attempt was made to adhere to this protocol, use of transthoracic countershock at any earlier time was left to the discretion of the staff at the bedside based upon the clinical status and hemodynamic stability of the patient during tachycardia.

"Burst" pacing through the catheter was attempted in 1 patient (Patient 5) with recurring episodes of ventricular tachycardia using a stimulus cycle length of 500 ms and current output of 15 mA.

Serial measurement of serum creatine kinase, lactic dehydrogenase, or glutamic oxaloacetic transaminase as an index of possible myocardial injury secondary to catheter countershock was not conducted. We could not reliably attribute elevations in enzyme levels to this technique since patients had received transthoracic countershock before insertion of the catheter and some had had an acute myocardial infarction.

Results

The catheter was inserted in 8 patients (Table I). Lead insertion was carried out uneventfully in the coronary care unit (5 patients) or in the electrophysiology laboratory (3 patients). Leads remained in position 1 to 16 days without a single lead displacement. Six of the 8 patients developed ventricular tachyarrhythmia requiring use of the countershock catheter.

Ventricular tachycardia: Synchronized cardioversion was attempted 99 times for 91 episodes of ventricular tachycardia (Fig. 3, Table II). Eighty-six (87%) of these attempts successfully terminated tachycardia using energy levels of 10 J or less. In 1 patient burst ventricular pacing was utilized to terminate ventricular tachycardia and was successful in 10 of 14 attempts (Fig.

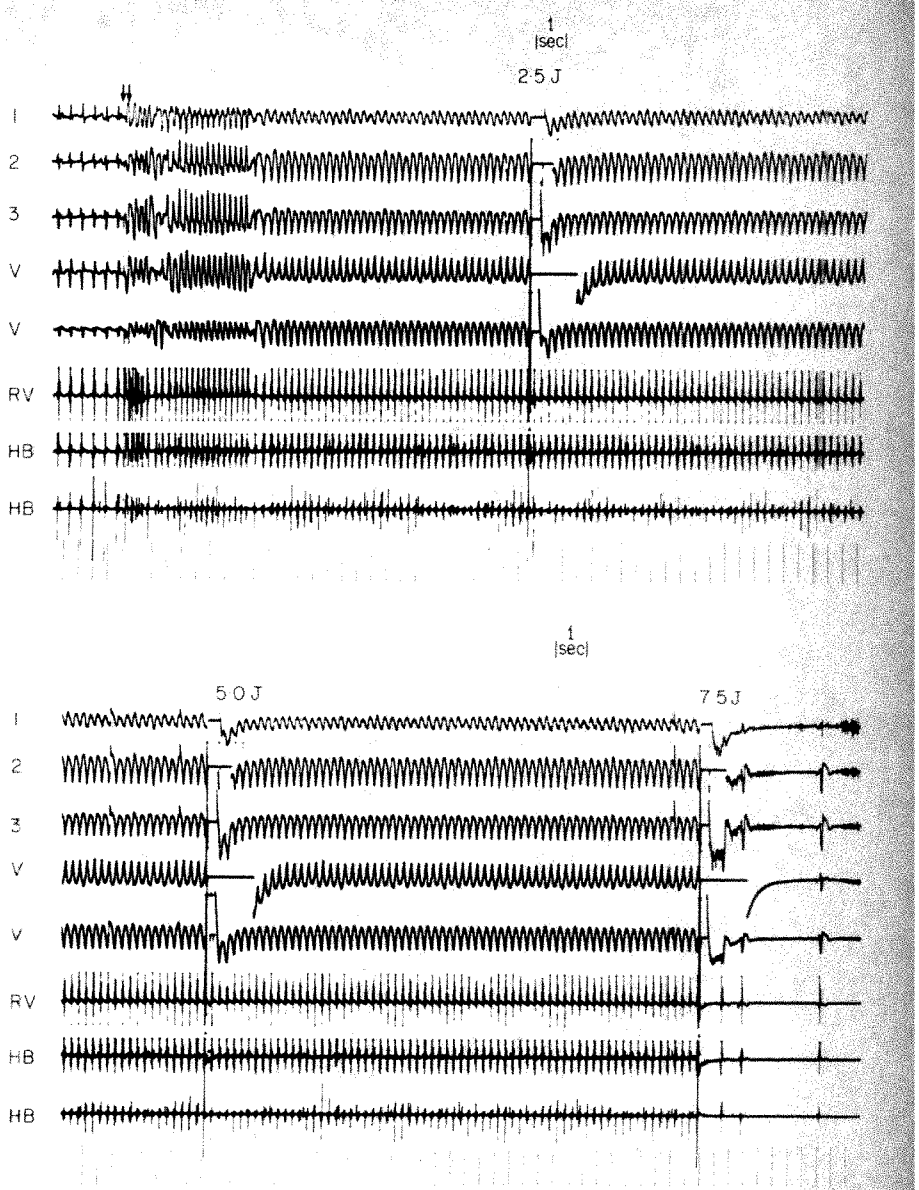

FIGURE 5. Continuous intracardiac recordings of ventricular tachycardia at electrophysiologic study. **Top,** the recording begins with ventricular tachycardia. The introduction of 2 premature ventricular stimuli (**arrows**) to terminate the tachyarrhythmia results in acceleration followed by a change in morphology of the tachycardia and hemodynamic deterioration. Catheter countershock attempt using 2.5 J fails to terminate ventricular tachycardia. **Bottom,** a second attempt using 5.0 J delivered through catheter lead also fails, but 7.5 J energy dose terminates ventricular tachycardia and restores sinus rhythm.

4). However, the use of programmed ventricular extrastimuli to terminate stable ventricular tachycardia in another patient led to acceleration of tachycardia with hemodynamic collapse (Fig. 5, top), necessitating the use of cardioversion by means of the catheter (Fig. 5, bottom).

Energy doses of 10 J or less failed to terminate 3 episodes of ventricular tachycardia (Patients 2, 3, and 5) and 2 other episodes did not terminate after 20 J (Patient 2). Transthoracic cardioversion using 200 J converted all 5 episodes.

Ventricular flutter and fibrillation: All 3 episodes of ventricular flutter occurring in 2 patients were converted with synchronized shocks of 7.5 J in 1 and 15 J in the other after a total of 5 attempts (Table II). There were 6 episodes of ventricular fibrillation requiring 11 attempts at catheter countershock. Four episodes were successfully terminated (Fig. 6), 1 at 5 J and 3 at 40 J. In 1 of the 2 failures (Patient 2), conventional defibrillation at 400 J successfully restored sinus rhythm. The second failure involving Patient 3 occurred as a preterminal event. Several attempts at conventional countershock in this patient resulted in asystole. In spite of successful pacing using an indwelling catheter, no cardiac output could be obtained.

Discomfort associated with catheter defibrillation: Discomfort was difficult to assess because most patients had a diminished level of consciousness at the time of countershock. However, shocks of 2.5 J were associated with a visible chest thrusting. One patient described a 2.5 J countershock as a "kick in the chest."

Clinical outcome: Satisfactory arrhythmia control was ultimately obtained in all 6 surviving patients. Two patients died in hospital with the catheter lead in situ. At the time of death, the lead was in satisfactory posi-

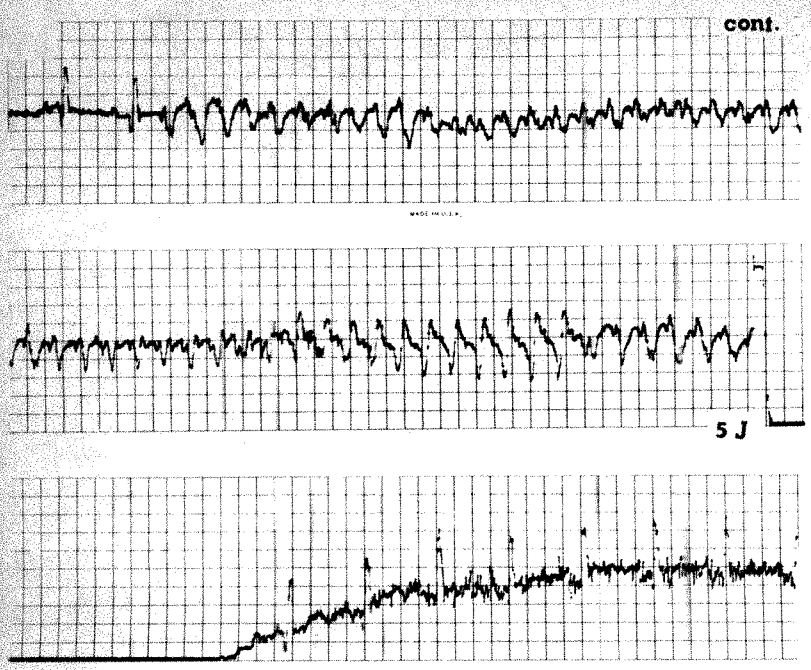

FIGURE 6. Patient 2. A continuous rhythm (lead II) strip shows sinus rhythm initially, with spontaneous development of ventricular fibrillation. Delivery of 5 J nonsynchronized shock using the catheter lead restores sinus rhythm.

tion in the right ventricular apex in both patients despite prolonged attempts at cardiopulmonary resuscitation. In 1 patient (Patient 3), a focal area of endocardial hemorrhage measuring less than 2 mm^2 was visible at the site of the proximal electrode (C and D). No gross or microscopic injury could be identified at the right ventricular apex. This patient had received 9 countershocks (25 to 40 J). The second patient had no identifiable injury as a result of 8 countershocks (2.5 to 5.0 J).

Discussion

Advantages of method: Patients with frequently recurring sustained ventricular tachyarrhythmia may require repeated cardioversion or defibrillation while effective antiarrhythmic management is being instituted. We have shown that the use of low energy countershock delivered through an intravascular catheter lead is feasible, effective, and safe in this setting. The countershock lead can be inserted with the relative ease of a temporary pacing lead and remains stable after initial placement. The system described offers several advantages over the conventional method of countershock. First, relatively low energy levels can be used with a potential for less myocardial necrosis after repeated countershocks.[1] Second, the catheter can be connected to a programmable stimulator for conversion of ventricular tachycardia by burst pacing or ventricular extrastimuli. Defibrillation can be carried out through the catheter in the event of acceleration of tachycardia. Third, the catheter can be used for pacing in the event of bradycardia or asystole. Finally, defibrillation can be carried out expediently with the patient in any position without the delay of placing paddles. Finally, low energy countershock is probably less traumatic to the still-conscious patient with deteriorating cardiac output than conventional countershock.

It is certain that the energies used for countershock in this study were greater than the minimal required energies using the catheter system.[2,3] Using our countershock system, we could not be certain of accuracy using stored energy less than 2.5 J. Furthermore, most countershocks were delivered by intensive care nursing personnel who could not be asked to titrate the minimal energy in patients with hemodynamic deterioration.

Comparison with previous lead systems: In 1970, Mirowski et al.[4] introduced the concept of an automatic internal defibrillator and conceived a lead system wherein a catheter placed at the right ventricular apex had 1 electrode in the right ventricle and a second separate electrode consisting of an apical subcutaneous plate. Subsequent designs incorporated both electrodes onto a single catheter,[5,6] and studies with various electrode positions demonstrated that the greatest efficacy of defibrillation was obtained when the distal electrode was placed in the right ventricular apex.[7] The optimal position of the proximal electrode (whether in the high right atrium or superior vena cava) was less critical so long as sufficient electrode surface area was present. However, in a review of their experience with the catheter mounted bielectrode lead, Mirowski et al.[8] noted that lead dislodgment was a significant problem leading to failure to defibrillate. We did not encounter lead displacement with the catheter (Medtronic DFX-2) used in this study. Newer prototypes of this catheter using fixation systems should minimize the problem of dislodgment.

Implications: Low energy countershock using an intravascular catheter is feasible in a clinical setting. Pacing, programmed stimulation, cardioversion, and

defibrillation can be performed with the catheter, resulting in more expedient arrhythmia management. In addition to its usefulness in the acute care setting, this technique could be adapted for use during electrophysiologic studies where ventricular tachyarrhythmia is anticipated. Finally, the potential exists for a completely "automated" bedside unit connected to the defibrillating catheter capable of detecting and treating both bradyarrhythmia and ventricular tachyarrhythmia.

Intraoperative 2-Dimensional Echocardiography: Ejection of Microbubbles From the Left Ventricle After Cardiac Surgery

PAUL C. RODIGAS, MD, FRANCES J. MEYER, BA, GEORGE B. HAASLER, MD, JEROME M. DUBROFF, MD, and HENRY M. SPOTNITZ, MD

Although the presence of entrapped air in the left ventricle at surgery has long been a concern, its prevalence and clinical significance are unknown. Two-dimensional echocardiography provides a unique means for observing intracardiac microbubbles intraoperatively. Accordingly, intraoperative 2-dimensional echocardiograms obtained in 79 patients immediately after cardiopulmonary bypass were examined for the presence of microbubbles. Left ventricular microbubbles were detected in 14% of coronary artery bypass operations (n = 22), 50% of multiple valve replacements (n = 8), 67% of single valve replacements (n = 58), and 100% of atrial septal defect closures (n = 4), left atrial myxoma resections (n = 2), and mitral commissurotomies (n = 2). Microbubbles were not observed in patients undergoing coronary artery bypass with valve replacement (n = 4) or with removal of left ventricular aneurysm (n = 1). Continuous ejection of microbubbles from the left ventricle was frequently noted for extended periods of time and, although no patient in this study showed evidence of gross neurologic dysfunction, the possibility of subclinical organ damage exists. We conclude that 2-dimensional echocardiography is useful for detection of intracardiac microbubbles and therefore may be instrumental in their elimination.

Air embolism is a dreaded complication of cardiac surgery.[1] The potential for embolism from both the cardiopulmonary bypass circuit and residual air in the left side of the heart appears to have been reduced by improved equipment and surgical techniques.[1] Nevertheless, the incidence of this problem might be further reduced by improved methods for detection of residual air in the left heart. The frequency and effects of air emboli have been studied in both clinical[2–4] and experimental[5–8] settings. Methods have included reflected[5] and Doppler ultrasound,[3] and direct visualization of the interior of the beating heart.[5] Unfortunately, many of these techniques necessitate apparatus too complex or invasive for routine intraoperative use. With others, sensors in the peripheral circulation may give inaccurate measurements due to streaming or dilution. Air is a high contrast medium in echocardiograms because of the difference in acoustic properties between air and blood.[9] Consequently, pulsed echocardiographic and A-mode and M-mode recordings have all been shown to be sensitive in detecting air microemboli, and intraoperative M-mode echocardiography has shown promise for detecting residual intracardiac air.[10] Two-dimensional echocardiography, however, allows visualization of the entire cross-section of the left ventricle in a single image, and image clarity is sufficient for detection of intracardiac air and microbubbles without specialized training.[11] Accordingly, in the present study, intraoperative 2-dimensional echocardiography was employed in 79 patients to determine the prevalence and clinical effects of residual air in the left ventricle at the conclusion of cardiac surgery.

Methods

Echocardiography during surgery: Informed consent for intraoperative echocardiography was obtained in 79 patients before cardiac surgery. Two-dimensional echocardiograms were recorded immediately before and after cardiopulmonary bypass with the patient cannulated as a precaution against arrhythmia. However, no intraoperative arrhythmias or other complications resulted. Images were obtained with a gas-sterilized hand-held 3.5 MHz phased-array ultrasound transducer and a V-3000 or V-3400 Ultrasonograph (Diasonics, Sunnyvale, California). Both short- and long-axis views of the left ventricle were recorded on videotape and examined later for the quantities of microbubbles. The transducer was gently applied to the anterior wall of the right ventricle, without a water path or deliberate introduction of fluid into the pericardium.[11] With experience, image recording could routinely be completed in less than 2 minutes. Myocardial preservation during surgery was provided by cold potassium cardioplegia.[12] Techniques for evacuation of air from the left side of the heart included decompression of the mitral valve, venting through the right superior pulmonary

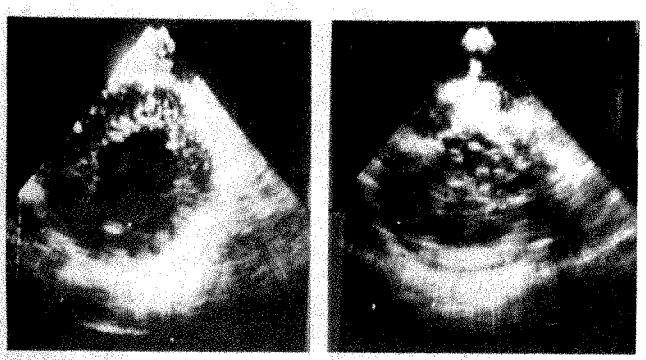

FIGURE 1. Microbubbles are illustrated in the left ventricle in 2-dimensional short-axis echocardiogram obtained at the conclusion of cardiopulmonary bypass after mitral and aortic valve replacement (**right panel**). Short-axis echocardiogram before surgery does not demonstrate this phenomenon (**left panel**).

vein, and final closure of atriotomies beneath a fluid level.[1] A small needle was placed in the ascending aorta and allowed to drain freely as left-sided cardiac output resumed at the conclusion of surgery to provide protection against possible air embolism.[1]

Echocardiographic interpretations: Microbubbles were apparent on intraoperative echocardiograms as bright reflections swirling within the lumen of the left atrium and left ventricle on short-axis sections and passing progressively from the left atrium to the left ventricle to the aorta on long-axis sections. The prevalence of air in the left heart was graded 0 to 3+ (0 = no air; 1+ = less than 5 microbubbles per frame; 2+ = moderate quantities of microbubbles, 10 to 25 per frame; 3+ = severe quantities of microbubbles, usually too many to count). The minimum number of bubbles detected in any study receiving a positive designation was 5. Echocardiograms before bypass were compared with those after bypass to facilitate accurate differentiation of air bubbles from artifacts.

Differences in surgical technique which might affect the prevalence of microbubbles were noted, and charts were reviewed for evidence of postoperative neurologic difficulty. The latter data were obtained retrospectively, and detailed neurologic examinations were not performed.

Results

Prevalence and severity of intraoperative microbubbles (Table I, Fig. 1): Overall, residual microbubbles were detected at the conclusion of cardiac surgery in 39 of the 79 patients (49%), and the prevalence of microbubbles was judged moderate or severe in 20 (25%). Microbubbles were detected in 14% of coronary artery bypass cases (n = 22), 67% of single valve replacements (n = 36), 50% of multiple valve replacements (n = 8), and 100% of atrial septal defect closures (n = 4), mitral commissurotomies (n = 2), and resections of left atrial myxoma (n = 2). Microbubbles were not observed in any patient undergoing combined procedures (coronary bypass plus valve replacement [n = 4] or plus left ventricular aneurysm resection [n = 1]). In some cases, microbubbles were detected being continuously ejected from the left ventricle for 5 minutes or longer after cardiopulmonary bypass, but the time course of microbubble concentration was not systematically studied.

TABLE I Prevalence of Microbubbles After Cardiac Operations

	Grading of Microbubbles				Patients	
Operation	0	1+	2+	3+	n	%
CABG	19	3	0	0	22	14
AVR	9	7	9	1	26	65
MVR	3	3	3	1	10	70
MC	0	0	1	1	2	100
XVR	4	2	0	2	8	50
ASD	0	3	1	0	4	100
LA myxoma	0	1	1	0	2	100
CABG + valve replacement	4	0	0	0	4	0
CABG + aneurysm	1	0	0	0	1	0
Total	40	19	15	5	79	49

Aneurysm = left ventricular aneurysm resection; ASD = atrial septal defect; AVR = aortic valve replacement; CABG = coronary bypass; LA = left atrial; MC = mitra commissurotomy; MVR = mitral valve replacement; XVR = multiple valve replacement.

Procedures requiring direct opening of the left atrium or left ventricle displayed the preponderance of intraoperative microbubbles. All patients receiving a 3+ designation underwent either aortic valve replacement, mitral valve replacement, double valve replacement involving at least 1 of these 2 valves, or mitral commissurotomy. All of the valve operations in which microbubbles were detected were left-sided procedures; no microbubbles were found in the 1 case of simple tricuspid valve replacement. No microbubbles were visualized in the left atrium or left ventricle before cardiopulmonary bypass, even with simultaneous cardiac output determinations producing clouds of microbubbles in the pulmonary artery. No large collection of residual air as a single bubble of substantial size was observed.

Correlation with surgical technique and methods of decompressing the heart: In general, surgical techniques were similar during valve replacements and differences could not be correlated with the degree of microbubbles present. Procedures utilized to decompress the left heart during coronary bypass were related to postoperative microbubbles as follows: 2 coronary bypass patients were vented with a catheter in the right superior pulmonary vein. Of these 2, rare microbubbles were subsequently detected in 1. A small number of microbubbles was also detected in 2 of 17 patients in whom decompression for coronary bypass was provided by suction on a cardioplegia needle in the ascending aorta.

Retrospective chart review demonstrated that during the period of this study no patient had neurologic impairment significant enough to be detected on routine physical examination, subjectively by the patient, or by the patient's family.

Discussion

Safety and sensitivity of technique: The present results demonstrate that intraoperative 2-dimensional echocardiography is a safe, convenient, and highly sensitive technique for detection of microbubbles in the

left ventricle at the conclusion of cardiac operations. This observation confirms previous conjecture based on M-mode echocardiography[10] and is consistent with previous clinical observations.[2–4] Indeed, it appears that the sensitivity of echocardiography in this regard is excessive, since no patient studied developed gross neurologic changes, even among those with continuous clouds of microbubbles ejected into the aorta (Table I). However, it has long been recognized that neurologic changes resulting from cardiac surgery may not be detected unless specific objective testing is employed.[13,14] Thus, at present it is not known whether the observation of clouds of microbubbles in the left ventricle is of clinical significance, although contrary observations have been reported.[3] Indeed, deliberate injection of microbubbles is the source of the "echocardiographic contrast effect" used to detect intracardiac shunts in neonates.[9,15] The quantity of microbubbles employed for clinical studies, however, appears small in comparison with the prolonged ejection of echo clouds in some of our patients. Moreover, since these microbubbles are too large to traverse normal capillary beds, they may produce some deficits, and it would be clearly desirable to strive to eliminate them. The lower limit of bubble size visible to ultrasound has been estimated to be 2 to 125 μm.[3,8,9,16]

Cause of microbubbles: Since intraoperative microbubbles are most prevalent when air must be admitted to the left atrium or left ventricle (for mitral or aortic valve replacement) and of low prevalence and in small amounts after coronary bypass, it is most probable that the bubbles represent foam which accumulates on the walls of the left ventricle, left atrium, and pulmonary veins[17] when they are refilled with blood. Consistent with this view, prior experimental studies have visualized small residual collections of air in the left ventricle of dogs during cardiac surgery.[5] A variety of possible wetting agents have been tested to reduce the prevalence of this problem, with paraldehyde the most effective of those applicable clinically.[5] Previous observations of intracavitary echoes early after mitral valve replacement may also represent microbubbles[18]; however, the effect we have observed usually disappears within 60 minutes after the conclusion of cardiopulmonary bypass.

Inconsistent with this view of the cause of microbubbles is our low observed incidence of the problem after operations combining coronary bypass with valve replacement or aneurysm resection. Since these procedures require increased duration of bypass between the time the heart is closed and all coronary anastomoses are completed, we speculate that all of the microbubbles present had been ejected from the heart before our echocardiographic studies. Since the number of patients in this group is small, the observations may not be representative.

Possible limitations of technique: The present results also suggest that intraoperative echographic studies might detect large bubbles of air in the left heart which could be aspirated or vented before left ventricular output is allowed to resume. We have not documented such a situation clinically, however. Finally, intraoperative 2-dimensional echocardiography is constrained by certain limitations for this purpose. Specifically, adequate images of the left heart require the presence of blood in the right ventricle, which serves the purpose of a stand-off and water path. For centers employing a double-cannulation technique, as we do, the presence of air in the right ventricle or a collapsed right ventricle, or both, will interfere with satisfactory imaging unless total bypass is converted to partial bypass or air is evacuated from the right ventricle by other measures.

Implications: Intraoperative 2-dimensional echocardiography is a sensitive method for detection of microbubbles ejected from the left ventricle at the conclusion of cardiac surgery, and appears promising for detection of larger amounts of air with lethal potential. The presence of microbubbles is most closely related to valve surgery requiring entry of air into the left ventricle. Although no clinical evidence of neurologic deficit was apparent in patients in this study, it would seem desirable to devise measures to limit the presence of postoperative microbubbles.

NOW IT'S HERE... ONCE-A-DAY 24-HOUR ANGINA PROPHYLAXIS

TRANSDERM®-NITRO

nitroglycerin

once-a-day

Transderm®-Nitro

nitroglycerin

Exclusive rate-controlling membrane delivers hour-by-hour precision dosage

- Specially designed copolymer membrane governs, and limits, rate at which drug diffuses from the system to the skin.
- Similar to an intravenous *infusion*, Transderm-Nitro delivers medication at a constant rate.
- Patients are protected against extremely high concentrations being reached even where skin is unusually permeable.

(actual size)

(approx. thinness)

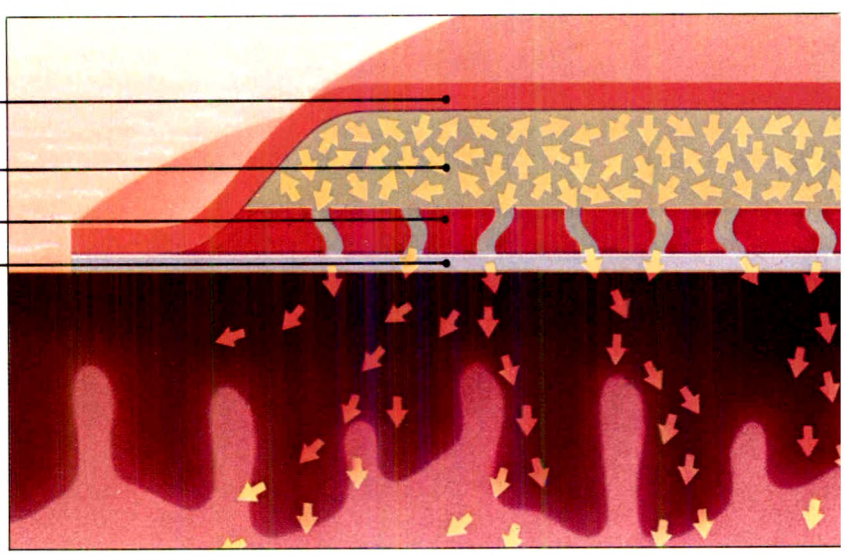
Magnified cross section of Transderm-Nitro system

impermeable water-resistant backing layer

nitroglycerin reservoir

rate-controlling membrane

hypoallergenic contact adhesive
Contains an initial dose of medication to saturate skin-binding sites so that absorption begins immediately



Precision dosage system assures 24-hour angina protection

Steady, sustained 24-hour nitroglycerin levels

Constant protection against angina attacks assured by uninterrupted plasma concentrations of nitroglycerin: Transderm-Nitro 5 rated to release 5 mg/24 hours; Transderm-Nitro 10 rated to release 10 mg/24 hours.

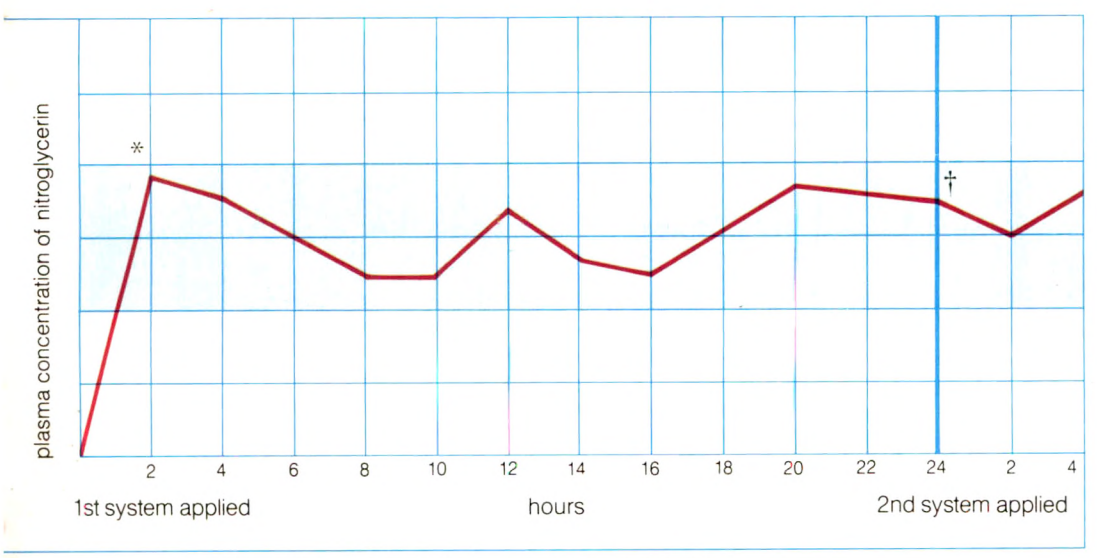
Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

System is simple and easy to use

- Every 24 hours the old system is removed and the new one applied.
- Therapeutic effect can be anticipated 30 minutes after application and maintained for 30 minutes following removal.
- Can be applied anywhere on the body except the distal extremities.

An advance beyond tablets and ointments

- 24-hour sustained therapeutic blood levels of nitroglycerin
- Precise dosage control
- Ease of administration...avoids mess and inconvenience of ointments
- Once-a-day dosage to enhance compliance
- May be worn while swimming, bathing and showering



*1st measurement in this study was taken 2 hours. However, a therapeutic effect can be anticipated 30 minutes after application of the system, and will be maintained for 30 minutes after its removal.

†After 24 hours, system is removed and a new one is applied to another site. Renewal of the system does not result in any significant alteration in the plasma levels, as long as the change is made without delay.

Transderm®-Nitro nitroglycerin

Once-a-day, 24-hour protection against angina attacks

System can be applied anywhere except distal extremities. Doesn't compromise daily activities.

Transderm®-Nitro
(nitroglycerin)
Transdermal Therapeutic System

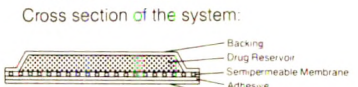
DESCRIPTION

Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface toward the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS

When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE

Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS

Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS

In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS

Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS

Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION

Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension, especially during orthostasis, indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS

A patient leaflet is supplied with the systems.

Impaired Collateral Blood Flow Reserve Early After Nontransmural Myocardial Infarction in Conscious Dogs

RANDOLPH E. PATTERSON, MD, BEVERLY A. JONES-COLLINS, MD, and ROGER AAMODT, PhD

The purpose of this study was to determine the adequacy of collateral blood flow reserve of surviving myocardium 3 to 4 days after coronary occlusion in dogs. The proximal circumflex coronary artery was occluded in 9 conscious dogs, and in 7 of these the mid-left anterior descending coronary artery was also occluded. Three to 4 days after myocardial infarction, studies were performed under control conditions and during right ventricular pacing at the maximal heart rate that did not decrease aortic pressure.

Pacing increased the heart rate from 110 to 222 beats/min, caused no change in mean aortic pressure (112 to 118 mm Hg), and increased left atrial pressure marginally (13.5 to 16.0 mm Hg) ($0.05 < p < 0.10$). The ischemic zone mass that was dependent on collateral flow because of coronary occlusion was 56% (range 29 to 69) of the mass of the left ventricle, and the mass of the infarct occupied 21% (range 4 to 41) of the mass of the left ventricle. Subendocardial and mid-myocardial ischemic zone samples contained infarcted tissue and had low control values of coronary vascular conductance (flow/100 mm Hg mean aortic pressure) which tended to decrease during pacing: subendocardium, 0.18 to 0.02 ml·min^{-1}·g^{-1}/100 mm Hg ($0.05 < p < 0.11$), and mid-myocardium, 0.38 to 0.11 ($p < 0.05$). Coronary vascular conductance in normal zone subepicardium increased 35% from control conditions to pacing (1.24 to 1.69 ml·min^{-1}·g^{-1}/100 mm Hg; $p < 0.03$). In contrast, coronary vascular conductance in surviving myocardium located in the subepicardial layer of the ischemic zone did not change during pacing (1.17 to 1.21 ml·min^{-1}·g^{-1}/100 mm Hg).

It is concluded that collateral blood flow in surviving myocardium within the initial zone of ischemia returns to normal under control conditions by 3 to 4 days after coronary occlusion, but there is no reserve capacity to increase collateral conductance. Impaired collateral reserve in this unique canine model is probably related to multivessel occlusion and to the short period of time collateral vessels had to develop (3 to 4 days after coronary occlusion). If these findings are clinically applicable, they suggest that severe stress after acute myocardial infarction has the potential to provoke ischemia and its consequences in the surviving tissue supplied by occluded coronary arteries.

Gradual coronary occlusion over days to weeks in the dog usually does not cause myocardial infarction and leads to a substantial increase in coronary collateral function so that myocardial blood flow approaches normal values at rest.[1–3] After gradual coronary occlusion, collateral flow reserve during stress has been reported to be either normal[4] or slightly subnormal[5–7] during stress in dogs.

In contrast to the gradual occlusion in the aforementioned studies, sudden coronary occlusion regularly causes myocardial infarction. A few hours to days after infarction, transmural mean blood flow to collateral-dependent myocardium is subnormal under resting conditions,[8–10] and the limited collateral flow that is available is redistributed from necrotic to surviving tissue.[8] This results in near-normal myocardial blood flow at rest in surviving tissue, an adaptation that might be expected to limit the development of additional ischemia. However, assessment of the reserve capacity to augment collateral myocardial blood flow is required to clarify the potential susceptibility of surviving myocardium to develop ischemia during stress.

Relatively little is known about collateral blood flow reserve after myocardial infarction. Recently, Hess and Bache[11] studied dogs 2 weeks after sudden occlusion of a single coronary artery. They found collateral myocardial blood flow during submaximal treadmill exercise to be 80% of normal in the tissue that contained minimal (1 to 25%) necrotic tissue, whereas flow was only 11% of normal in tissue that contained 75 to 100% necrotic tissue. These data indicate good collateral flow reserve during exercise in tissue with little or no necrosis 2 weeks after single vessel coronary occlusion.

The aforementioned study[11] was not designed to assess collateral flow reserve either early after myocardial infarction or in the presence of multivessel coronary disease. Because complications occur more frequently in patients in the first days after infarction[12] and in patients with multivessel coronary disease,[13] the purpose of the present study was to assess collateral blood flow reserve 3 to 4 days after myocardial infarction in dogs with occlusion of 2 coronary arteries. We also assessed factors that might influence collateral flow and its response to stress. The experimental model of 2 vessel coronary occlusion used in the present study was extremely difficult because of the high death rate, but it may offer some unique features with potential relevance to human acute myocardial infarction.

Methods

Experimental preparation: We anesthetized 41 foxhound dogs with sodium amytal, nitrous oxide, and halothane. Under sterile conditions, a thoracotomy was performed in the fourth left intercostal space and a polyethylene catheter was placed into the left internal mammary artery. We next opened the pericardium and dissected the left circumflex coronary artery near its origin (before any major ventricular branches), and the left anterior descending coronary artery in its mid-portion (after the second or third left ventricular branches). A deflated balloon occluder (Brunswick Manufacturing, Quincy, Massachusetts) was positioned around the circumflex coronary artery and snares (1-0 silk inside a plastic catheter) were placed around both coronary arterial branches. Great care was taken to anchor the balloon and snare occlusive devices so that they would not cause coronary occlusion until the desired time. A polyethylene catheter was then inserted through a stab wound in the left atrial appendage and secured in the left atrium. Finally, a 3-pronged electrode plate was secured by sutures on the epicardial surface of the outflow tract of the right ventricle. The connectors from all of the implanted instruments were tunneled under the skin to a subcutaneous pouch at the base of the neck. The catheters were filled with heparin, 1,000 U/ml, sealed by a knot and a heat-seal at the tip, and the chest was closed in layers. The dogs were trained to lie on their right side in a quiet, dimly lit room during the period of recovery from surgery.

Protocol: After recovery from surgery for 1 to 3 weeks, each dog received morphine, 1 mg/kg, and local anesthesia with lidocaine to exteriorize the connectors from the subcutaneous pouch. The catheters were connected to Statham P23Db transducers to measure continually aortic and left atrial pressure, along with an electrocardiogram on a Sanborn model 350 physiologic recorder. Each dog received lidocaine, 1 mg/kg, as an intravenous bolus and a 2 to 3 mg/min continuous infusion before inflation of the pneumatic occluder on the circumflex coronary artery. The occluder was inflated with saline solution to one fourth of the volume that had been required at the time of surgery to cause coronary occlusion. Every 15 minutes an additional one fourth of this volume was injected into the occluder until the circumflex coronary artery was totally occluded (45 minutes after the beginning of balloon inflation). The circumflex artery snare was pulled and secured to ensure total permanent occlusion as soon as the last volume

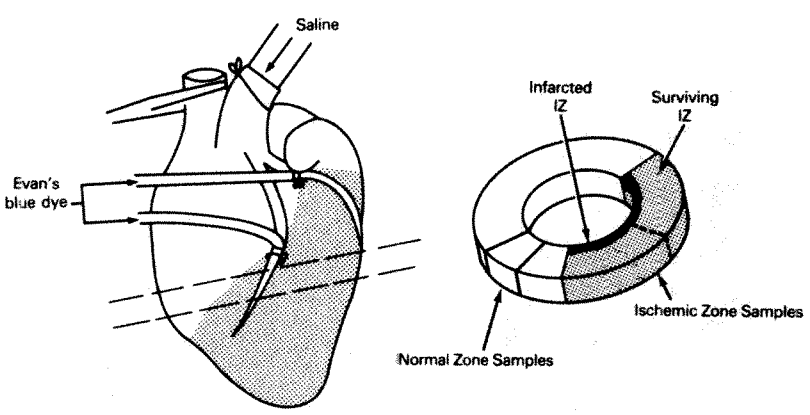

FIGURE 1. Diagram of postmortem methods to identify ischemic zone and myocardial infarction. **Left,** diagram of a dog heart showing how the circumflex and left anterior descending coronary arteries were perfused by cannulas inserted distal to the points of occlusion. These arteries were perfused with Evans blue dye at the same pressure as the other unoccluded coronary arteries, which were perfused with fluorosine through the aortic root. The left ventricle was cut into 4 to 5 mm thick doughnut-shaped slices, one of which is shown in the diagram **at the right.** The blue-stained ischemic zone was marked on both sides of each slice by a careful incision at the border between blue and fluorosine dye, and each slice was incubated in triphenyl tetrazolium to stain the surviving tissue red. Each slice was photographed on both sides for integration of areas of the normal, ischemic (IZ), and myocardial infarction zones. The average area of normal zone, ischemic zone, and myocardial infarction, for both sides of each slice was multiplied by the weight of each slice to give the total mass of normal, ischemic, and myocardial infarction zones for the entire ventricle. Samples were dissected from normal and ischemic zones, as shown, to count microsphere radioactivity for myocardial blood flow. Ischemic zone samples were at least 10 mm inside the blue-stained border to avoid normal zone contamination, and samples were divided into transmural thirds from subendocardium, mid-myocardium, and subepicardium.

of saline solution had been injected into the balloon. Five minutes after circumflex artery occlusion, we pulled and secured the left anterior descending snare in all dogs in which mean left atrial pressure had not increased above 15 mm Hg. The dogs were monitored and received lidocaine for 3 to 5 hours after coronary occlusion. We began coronary occlusion on 41 dogs, and 27 died within the first day after occlusion. Thus 14 dogs survived 3 to 4 days. The pacemaker electrodes did not work in 2 of these dogs, and 2 died from ventricular fibrillation during right ventricular pacing (200 to 240/min). One dog did not receive radionuclide-labeled microspheres because of left atrial catheter failure, so 9 dogs were studied. Of these 9 dogs, 7 had 2 vessels occluded, and 2 had circumflex artery occlusion alone because left atrial pressure had been over 15 mm Hg 5 minutes after circumflex artery occlusion.

Myocardial blood flow measurements: These 9 dogs received morphine, 1 mg/kg, 3 to 4 days after coronary occlusion, and their catheters and right ventricular pacing wires were exteriorized. Thirty minutes after beginning continuous electrocardiographic and pressure monitoring we injected 2 million 15 μm diameter microspheres labeled with one of the following radionuclides: iodine-125, cerium-141, chromium-51, strontium-85, niobium-95, or scandium-46 (3M, St. Paul, Minnesota). A reference sample of aortic blood was withdrawn at 15.2 ml/min beginning before and continuing for 90 seconds after microsphere injection. The reference blood sample was not collected adequately during either the control or pacing period in 4 dogs. Criteria for inadequate collection were failure to turn on the aortic blood withdrawal pump before microsphere injection (n = 2) and having the blood withdrawal stop within the first 60 seconds after microsphere injection because of clotting in the aortic catheter (n = 2). Thus, in these dogs only relative blood flow to different regions of the heart (ischemic zone versus normal zone) could be measured. This ratio of blood flows is useful because it relates the blood supply to the ischemic region to the normal region where patent coronary arteries allow autoregulation to match blood supply to metabolic demands.[1,2] Two of these 4 dogs were the dogs with single vessel occlusion. After the control measurements, we paced each dog's right ventricle to 200/min and increased pacing by 20/min every 15 to 30 seconds until there was a decreasing mean aortic pressure. We waited 15 minutes and resumed pacing at 20/min slower than the maximum. After 2 minutes of pacing, we measured pressures and injected microspheres labeled with a different radionuclide. Pacing was continued 1 to 2 minutes after microsphere injection to allow microspheres to distribute to tissues. The dogs were euthanized with an overdose of pentobarbital.

Postmortem analyses: We cannulated each occluded coronary artery distal to the site of its occusion and the aorta 1 to 2 cm above the coronary ostia (Fig. 1). The dye reservoirs were positioned high above the heart to perfuse the coronary arteries at the same pressure as the aorta (100 mm Hg), delivering fluorosine into the aorta and Evans blue dye into the coronary arteries distal to their sites of occlusion.[14] Thus, the regions supplied by the occluded arteries and therefore dependent on collateral flow and potentially ischemic, were identified by blue stain. Myocardium supplied by patent arteries was identified by the fluorosine stain. After removing the atria and right ventricle, we cut each heart into 8 to 10 doughnut-shaped slices, 4 to 5 mm thick, from apex to base (Fig. 1). Each slice was carefully dissected to make an incision along the irregularly shaped boundary between blue and fluorosine stains on both sides of each slice. We incubated each slice in triphenyl tetrazolium for 1 hour at 37°C to stain noninfarcted tissue red. The heart slices were preserved in 10% buffered formalin for 24 hours and then each side was individually photographed. The photographic slides were projected to trace the outlines of the total left ventricular slice, potentially ischemic zone (marked by previous incisions), and the tetrazolium-negative region of myocardial infarction (Fig. 1). The areas of each region were integrated for each side of the heart slice, averaged, and multiplied by the weight of each slice to yield the masses (g) of the left ventricular slice, ischemic zone, and myocardial infarction region for each slice. The total masses of each region were summed for all slices to yield the total masses of the left ventricular ischemic zone and myocardial infarction.

Finally, we dissected samples from the normal zone remote from the ischemic zone, and from the center of the circumflex-dependent ischemic zone at least 1 cm inside the incision that marked the boundary between the ischemic and normal zones. These samples for microsphere radioactivity counting were divided into subendocardial, mid-myocardial, and subepicardial layers. The samples were weighed and counted in appropriate energy windows. Counts were corrected for crossover activity from other radionuclides by a decontamination matrix of simultaneous linear equations, as previously described.[15] Myocardial blood flow was calculated by the following formula: (tissue counts)·(sample weight)$^{-1}$·(refer-

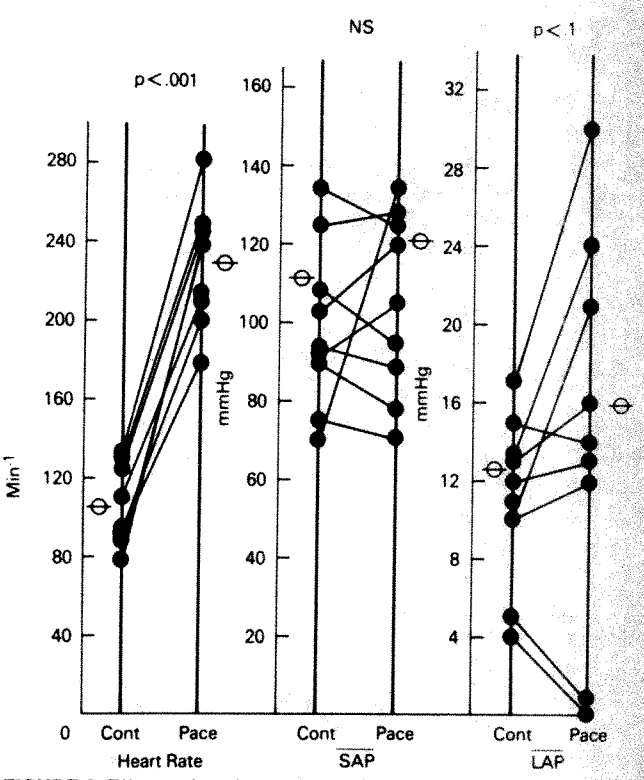

FIGURE 2. Effects of pacing-tachycardia on systemic hemodynamics 3 to 4 days after myocardial infarction. These 3 graphs show values for heart rate (beats·min^{-1}), mean aortic or systemic arterial pressure ($\overline{SAP}$, mm Hg), and mean left atrial pressure ($\overline{LAP}$, mm Hg). Data for the same dog are shown by **closed circles** and connected by **lines** from the control (Cont) value on the **left** to the value during pacing (Pace) on the **right** in each of the 3 graphs. The mean values of each variable during each condition are shown by the **open circles** beside each **bar.** The p values shown above each graph resulted from paired Student's *t* tests (n = 9).

ence blood sample counts)$^{-1}$·(rate of withdrawal of the reference blood sample).[16] Because the major focus of the present study was on the measurements made a few minutes before the animals' death, we did not attempt to calculate microsphere loss in these studies.[15]

Data analysis: We tested the significance of changes in variables between control and pacing periods by Students' *t* test for paired data. The best fit equation (least squares linear regression) was calculated, as was the correlation coefficient (*r*).[17] P values less than 0.05 were considered significant, and p values less than 0.1 but greater than 0.05 were reported as marginally significant.

Results

Sizes of ischemic and infarct zones: The mass of the ischemic zone averaged 56% of the left ventricle (range 38 to 69), the mass of the myocardial infarction averaged 21% of the left ventricle (range 4 to 41), and the mass of the infarct averaged 32% of the ischemic zone (range 7 to 74). Gross examination of specimens stained by tetrazolium before microsphere counting revealed some myocardial infarction in all samples from the subendocardium and in some samples from the mid-myocardium, but in no samples from the subepicardium.

Hemodynamics: Figure 2 shows heart rate, mean aortic pressure, and left atrial pressure during control and pacing periods 3 to 4 days after myocardial infarction. Right ventricular pacing increased the heart rate twofold, caused no change in mean aortic pressure, and caused a marginal increase in left atrial pressure ($0.05 < p < 0.1$).

Myocardial blood flow: The average transmural myocardial blood flow to the normal zone was 1.67 ml·min^{-1}·g^{-1} during control conditions and increased to 2.21 during pacing (n = 5). Mean transmural blood flow to the ischemic zone was reduced 3 to 4 days after infarction ($p < 0.05$), and did not change during pacing (0.54 to 0.49 ml·min^{-1}·g^{-1}). Because some dogs showed changes in aortic pressure, we calculated coronary vascular conductance (myocardial blood flow per 100 mm Hg mean aortic pressure). Pacing in the 5 dogs with all microsphere blood samples available increased mean transmural vascular conductance to the normal zone (Fig. 3, top) ($p < 0.03$), whereas mean transmural collateral conductance to the ischemic zone was lower at rest and did not change during pacing (Fig. 3, bottom). When each transmural layer was analyzed individually, the subendocardial and mid-myocardial collateral vascular conductances were low at rest and tended to decrease further during right ventricular pacing ($p < 0.11$ and $p < 0.05$, respectively). Collateral vascular conductance to the subepicardial layer of the normal zone increased during pacing from 1.21 to 1.61 ml·min^{-1}·g^{-1}/100 mm Hg ($p < 0.05$). In contrast, vascular conductance to the surviving subepicardial layer of the ischemic zone was normal at rest and did not increase during pacing stress (1.17 to 1.21 ml·min^{-1}·g^{-1}/100 mm Hg).

Relation of collateral flow reserve to hemodynamics and extent of infarction: We analyzed the potential influence of several factors on collateral flow and its reserve capacity to increase during pacing stress, 3 to 4 days after infarction. The fraction of the ischemic zone that developed myocardial infarction correlated closely with resting subendocardial flow ($r = 0.87$), but not with resting subepicardial flow ($r = 0.43$) (Fig. 4). These correlations indicate that 3 to 4 days after infarction collateral blood flow in the infarcted subendocardium is related closely to the extent of infarction. In contrast, collateral blood flow to the surviving subepicardial layer is nearly normal and relatively independent of the extent of infarction. Pacing tends to decrease the relative distribution of flow to the ischemic zone for any given extent of infarction, although the correlations between flow (ischemic zone/normal zone)

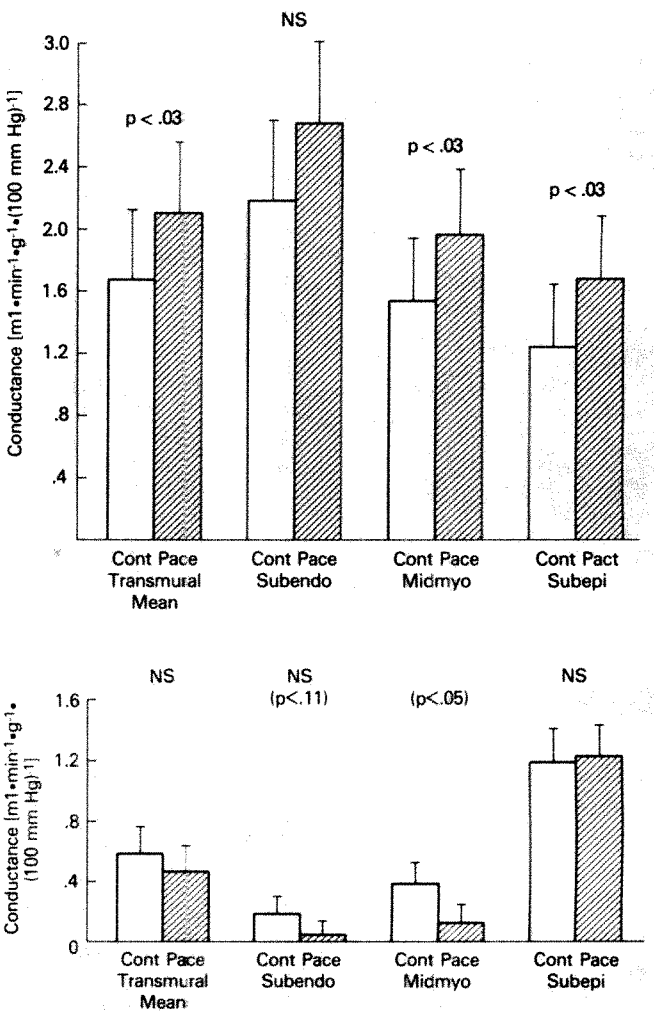

FIGURE 3. Effects of pacing-tachycardia on coronary vascular conductance 3 to 4 days after myocardial infarction. **Top,** data for the normal zone and **bottom,** data for the ischemic zone. Coronary vascular conductance was calculated as myocardial blood flow divided by mean aortic pressure, (ml·min^{-1}·g^{-1}/100 mm Hg). Data are shown for the following samples: transmural mean, subendocardial (subendo), midmyocardial (midmyo), and subepicardial (subepi). The **clear bars** show the control (Cont) values and the **shaded bars** the values during pacing (Pace). The p values resulted from paired Student's *t* tests. The brackets show 1 standard error of the difference (n = 5 because of problems with collecting reference arterial blood samples in 4 of 9 dogs).

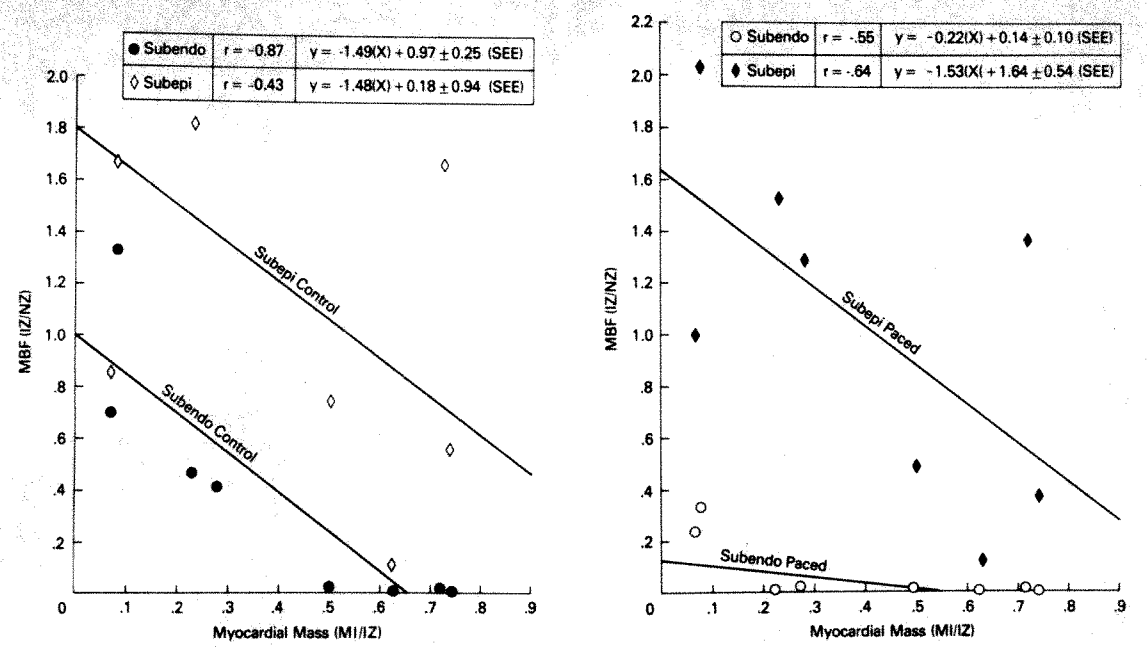

FIGURE 4. Relations between the myocardial blood flow (MBF) ratio, ischemic zone/normal zone (IZ/NZ), and the fraction of the ischemic zone that is infarcted (MI/IZ) 3 to 4 days after infarction. **Left,** during control conditions, and **right,** during pacing-tachycardia (n = 9). **Left,** the **closed circles** represent data for the subendocardium, and the **open circles,** diamond-shaped symbols for the subepicardium. The **boxed area** shows the correlation coefficients (*r*) and equations for the linear regression lines, ± the standard error of the estimate (SEE). **Right,** the symbols are shown in **the box.** Note that the best correlation between blood flow (IZ/NZ) and the fraction of the ischemic zone that undergoes infarction (MI/IZ) is found for the subendocardium under control conditions ($r = -0.87$). Subepicardial samples (which had no gross evidence of infarction) have more blood flow for any given percent infarction during control or pacing conditions (n = 9).

and size of myocardial infarction (myocardial infarction mass/ischemic zone mass) are not strong ($r = -0.55$ for subendocardium and $r = 0.64$ for subepicardium).

Figure 5 shows a fair correlation between collateral flow 5 minutes after coronary occlusion versus 3 to 4 days after occlusion during pacing ($r = 0.73$), suggesting that collateral flow reserve 3 to 4 days after myocardial infarction depends in part on preexisting collateral flow. The initial collateral flow 5 minutes after coronary occlusion does not permit quantitative prediction of collateral flow reserve 3 to 4 days after acute myocardial infarction. Figure 6 shows the lack of relation between the left atrial pressure and subepicardial collateral flow during control ($r = 0.44$) and pacing ($r = 0.29$).

Discussion

The major objective of the present study was to determine whether the coronary vascular conductance to surviving myocardium has the reserve capacity to increase during pacing tachycardia 3 to 4 days after acute myocardial infarction. We also examined factors that might influence collateral flow reserve 3 to 4 days after infarction. The design of the present study differs from most previous reports in that the dogs had myocardial infarction before collateral blood flow reserve was tested. Most physiologic studies of coronary collateral function have been designed to avoid myocardial infarction.[8] Collateral reserve after myocardial infarction and multivessel coronary occlusion was studied because inadequate collateral blood flow reserve in surviving myocardium might predispose the heart to further ischemia and infarct extension after the initial acute myocardial infarction. This relation might be expected because myocardial infarction size has been found related to the collateral myocardial blood flow available a few minutes after coronary occlusion.[8–10,18]

One previous study by Hess and Bache[11] found only a moderate reduction in collateral blood flow to regions with minimal myocardial infarction during exercise in dogs 2 weeks after acute occlusion of a single coronary vessel. The present study design differed from the previous study in 2 major ways: Collateral blood flow reserve was assessed earlier (3 to 4 days) after acute coronary occlusion, and 2 major coronary vessels were occluded in 7 of the 9 animals studied. The experimental model of multivessel coronary disease 3 to 4 days after myocardial infarction seems relevant to the patients in whom complications of myocardial infarction are most likely to develop in the clinical situation,[12,13] but the exceedingly high death rate of these dogs limits the number of animals that can realistically be entered into a study.

Coronary vascular conductance at rest and during pacing tachycardia: The results of the present investigation indicate that coronary vascular conductance at rest in collateral-dependent myocardium 3 to 4 days after acute coronary occlusion is reduced in subendocardial and mid-myocardial layers. These regions contain grossly visible infarcted tissue. Pacing stress led to a further decrease in vascular conductance in these deep layers. In contrast, collateral conductance at rest returned to values equal to that in the normal

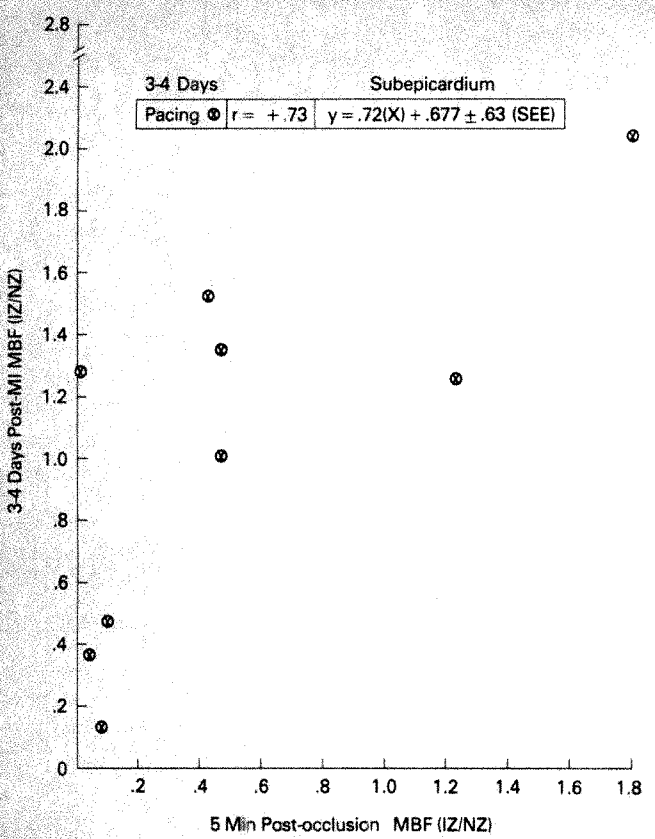

FIGURE 5. Relation between the myocardial blood flow (MBF) ratio, ischemic zone/normal zone (IZ/NZ) in the noninfarcted subepicardium 5 minutes after coronary occlusion versus 3 to 4 days later, after myocardial infarction, during pacing-tachycardia . Other symbols and abbreviations as in Figure 4 (n = 9). Note that the index of collateral blood flow reserve (IZ/NZ during pacing) 3 to 4 days after myocardial infarction correlates moderately well with the initial collateral blood flow available 5 minutes after coronary occlusion ($r = 0.73$). The initial collateral flow ratio does not allow quantitative prediction of subsequent collateral flow reserve.

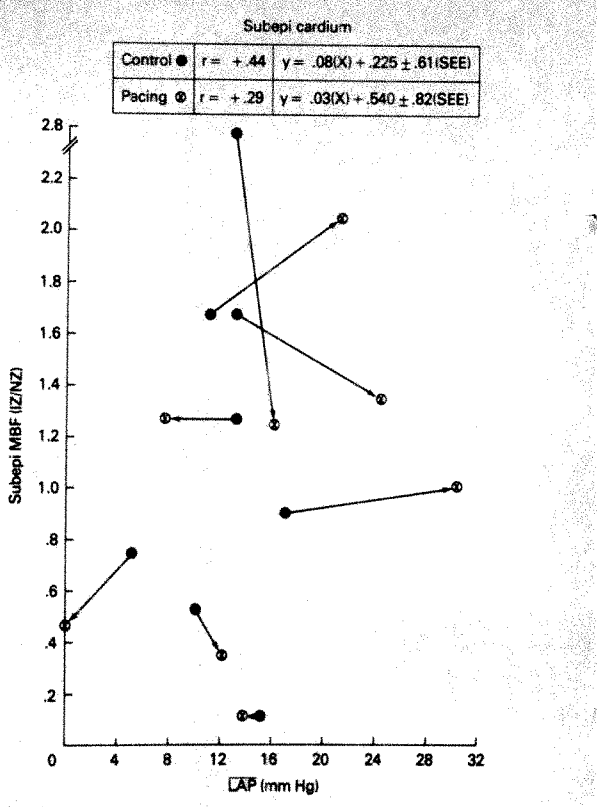

FIGURE 6. Relation between the myocardial blood flow ratio (ischemic zone/normal zone) and mean left atrial pressure during control (**closed circles**) versus pacing (**x inside circles**) conditions, 3 to 4 days after infarction. Note that there is no particular relation between the changes in blood flow and left atrial pressure during either control or pacing periods, 3 to 4 days after infarction. Other symbols and abbreviations as in Figures 4 and 5 (n = 9).

zone in the subepicardial layers. Nonetheless, vascular conductance did not increase in the surviving collateral-dependent subepicardial layers during pacing to the same extent that it did in normal myocardium that lay outside the collateral-dependent zone. The potential functional significance of this finding will be discussed after a critique of our methods.

Methodology: Several methodologic considerations are important to consider. First, dogs were studied in the awake state to avoid the effects of anesthesia and acute surgical trauma. Second, we defined the presence or absence of myocardial infarction by examination of both surfaces of heart slices 4 to 5 mm thick after staining with triphenyl tetrazolium. The ability of this staining technique to distinguish necrotic from surviving tissue within the vascular distribution of the occluded coronary artery has been validated in this laboratory by histopathologic examination.[14] Some myocardial infarction was found in all of the subendocardial samples and most mid-myocardial samples that were used for microsphere measurements of blood flow. In contrast, none of the subepicardial samples manifested any evidence of infarction. Although large regions of myocardial infarction could be excluded by the method employed, it is possible that a small amount of necrotic tissue existed in the subepicardial samples. Even if these samples contained up to 10% necrotic tissue with zero blood flow, this would cause our microsphere blood flow measurements to underestimate true collateral myocardial blood flow by only 10%. Thus, it is unlikely that our conclusion that subepicardial collateral vascular conductance does not increase normally 3 to 4 days after myocardial infarction is due to an artifact resulting from the presence of necrotic tissue in the samples.

Third, if the samples of supposedly ischemic myocardium used for collateral flow measurements had included some overlapping tissue dependent on an unoccluded coronary artery, then our measurement of apparent collateral blood flow might be increased artifactually. This artifactual increase in collateral myocardial blood flow is most serious during interventions that increase blood flow through normally patent coronary arteries.[19] In the present study we minimized the likelihood of this artifact influencing our results by injecting dye into the coronary arteries distal to their sites of occlusion and dissecting samples from at least 10 mm inside the dye-stained border. In other studies using

similar dye injection methods and a microsphere technique to label tissue supplied by normally patent arteries, the overlapping normal tissue was located primarily in the subendocardium[20] and was less than 5 mm from the lateral border of the dye-stained zone.[8,20,21] Further, the increase in normal zone blood flow in the present study were not large enough to cause a large artifactual increase in apparent collateral blood flow. These considerations indicate that no significant contribution to subepicardial collateral blood flow would be expected from overlapping normal zone tissue in the present study.

Fourth, right ventricular pacing does not stimulate a maximal increase in coronary blood flow. Studies in man[22] and dog[7] have indicated that exercise causes a greater increase in coronary blood flow than does pacing to the same heart rate. However, after adjusting the increase in coronary blood flow for the increased aortic pressure during exercise, exercise appears to cause only a 30 to 50% greater increase in coronary vascular conductance than does pacing to the same heart rate.[7,22] Thus, the failure of collateral blood flow to increase in surviving subepicardial tissue during pacing does not appear to be an artifact of an inadequate stimulus to collateral blood flow. The tachycardia-stress employed in the present study is a stress that frequently occurs in patients with tachyarrhythmias 3 to 4 days after myocardial infarction.[12]

Fifth, pacing was performed for 2 minutes before and 1 to 2 minutes after microsphere injection to ensure tissue distribution. No major hemodynamic changes were noted during pacing probably because the rate had been selected from previous tests in the same dog to ensure stable mean arterial pressure. Left atrial pressure increased in 4 dogs by more than 3 mm Hg, decreased by 3 mm Hg in 2 dogs, and did not change in 3 dogs (Fig. 2). Changes in left atrial pressure were not related to changes in heart rate, aortic pressure, collateral myocardial blood flow (Fig. 6), or myocardial infarction size.

Sixth, the present study measured blood flow reserve in collateral-dependent myocardium 3 to 4 days after acute myocardial infarction, but we did not measure an index of ischemic injury during pacing stress. Thus, the conclusions are related specifically to collateral blood flow reserve—a major determinant of the potential for ischemia—rather than to the severity of ischemia itself. We did express collateral blood flow reserve as a fraction of the flow reserve measured simultaneously in the regions of the left ventricle supplied by patent coronary arteries. These normal regions of the heart should show autoregulatory changes in blood flow to reflect the level of myocardial oxygen demand at the time of collateral blood flow measurements.[4]

Mechanisms influencing collateral flow: Several mechanisms probably contribute to limited collateral myocardial blood flow reserve after myocardial infarction. *First, occlusion near the origin of the circumflex and the mid-portion of the left anterior descending coronary arteries rendered 56% of the left ventricle ischemic in the present study.* Occlusion of 2 of 3 vessels deprives the heart of 1 of its 2 potential sources of collateral vessels that would be available after single vessel occlusion. This effect contributes to the observation that collateral myocardial blood flow decreases as a larger fraction of the left ventricle is rendered ischemic by coronary occlusion.[23,24] Multivessel occlusion in 7 of 9 dogs in the present study must have contributed to the fact that we observed lower collateral flow reserve than have others.[11] Also, the dogs' individual variability in collateral development probably influences collateral flow reserve 3 to 4 days after infarction. This is suggested by Figure 5, which indicates a reasonable correlation between collateral flow reserve 3 to 4 days after infarction and the initial collateral flow 5 minutes after coronary occlusion ($r = 0.73$).

Second, 3 to 4 days after acute coronary occlusion the coronary collateral vessels would be in only an early stage of their growth transformation process, which usually takes 4 to 6 months.[2,7] The early days of collateral development appear to be associated with less flow reserve than is found later.[2–7] Thus, the brief time available for collateral development undoubtedly contributed to the more severe impairment of subepicardial blood flow reserve observed in the present study compared with the moderate impairment reported by others 2 weeks after acute occlusion.[11]

Third, the 9 dogs studied were selected from 14 survivors of multivessel occlusion. Most of the 41 dogs subjected to these coronary occlusions in the awake, sedated state died within a few hours. The relatively high blood flow to normal zone myocardium after occlusion of 2 coronary arteries probably reflects reflex stimulation of the heart to maintain the circulation after the large myocardial infarction. Thus, the surviving dogs selected for study may differ from the general population of dogs in ways that could influence their subepicardial blood flow reserve measured after infarction. It seems most likely that the selection process would have favored dogs with better collateral flow reserve, again making our results conservative in estimating the severity of the flow deficit.

Fourth, impaired collateral flow reserve in the surviving subepicardium may be explained in part by the decreased diastolic time per minute during pacing, because collateral coronary flow occurs primarily during diastole.[25,26] The level of left atrial pressure during pacing (16 mm Hg) did not appear to inhibit subepicardial collateral flow, as indicated by the poor correlations between left atrial pressure and its changes and subepicardial collateral flow (ischemic zone/normal zone, $r = 0.29$ during pacing). This lack of effect of left ventricular filling pressure on subepicardial collateral flow reserve is not surprising because left ventricular diastolic pressure exerts its major inhibitory effect on collateral blood flow in the subendocardium.[27–30]

Clinical implications: The validity of extrapolating from animal studies to human disease is always uncertain. Man may have less potential for collateral vessel development than does the dog, which suggests that the present animal study may be conservative in that it estimates better coronary collateral flow than is present

in patients 3 to 4 days after acute myocardial infarction.[31] It is likely that there is overlap between the status of collateral flow development in individual patients and animals. If this is so, then the results of this study suggest that some patients with multivessel coronary disease have inadequate collateral blood flow reserve capacity 3 to 4 days after myocardial infarction.

The present study should not be interpreted as evidence that early mobilization of patients with an uncomplicated clinical course after acute myocardial infarction is necessarily dangerous. Rather, these data in animals support a "common sense approach" to early mobilization.[32] If early mobilization caused a large increase in heart rate, most cardiologists would advise a decrease in the level of physical activity.[33] Further clinical data suggest the feasibility of discharging carefully selected patients 1 week after myocardial infarction[34] or of treadmill stress testing 2 to 4 weeks after myocardial infarction.[35,36] These clinical practices have been restricted to carefully selected subgroups of patients,[32–36] who probably differ from these animals with multivessel disease 3 to 4 days after a large myocardial infarction. Further, the demonstration of impaired collateral flow reserve in the present study may be relevant to the mechanism of positive stress tests after acute myocardial infarction.[35,36]

Relation Between Regional Distribution of Thallium-201 and Myocardial Blood Flow in Normal, Acutely Ischemic, and Infarcted Myocardium

ALAN CHU, MD, ROBERT H. MURDOCK, Jr., MA, and FREDERICK R. COBB, MD

Myocardial localization of thallium-201 was compared with direct measurements of myocardial perfusion in normal, acutely ischemic, and recently infarcted myocardium. Studies were performed in 6 chronically instrumented dogs that were subjected to myocardial infarction by occlusion of the proximal left circumflex coronary artery. Four days after myocardial infarction, thallium-201 and 9 ± 1 μm niobium-95-labelled microspheres were injected simultaneously after acute left anterior descending coronary arterial occlusion; the animals were killed 5 minutes later and the entire left ventricle was sectioned into 1 to 2 g samples. Regression analyses between thallium-201 activity and regional myocardial blood flow using all myocardial samples demonstrated a very close linear relation in each dog; *r* values were 0.98 or greater, indicating that the initial localization of thallium-201 in acutely ischemic and recently infarcted myocardium as a function of regional blood flow was essentially identical. Consequently, in each dog the regional distribution of thallium-201 closely approximated myocardial perfusion over a wide range of blood flow and potentially different local metabolic conditions that may be encountered in the clinical use of the isotope.

Thallium-201, a biologically active ion, is the most commonly used tracer isotope for evaluating regional myocardial perfusion. Thallium-201 scintigraphy is used to assess transient myocardial ischemia induced by exercise stress[1–3]; evaluation is commonly required in the presence as well as absence of prior myocardial infarction. Thallium-201 scintigrams have been recorded serially after acute myocardial infarction as measurements of initial and subsequent dimensions of the ischemic zone (that is, a thallium-201 deficit that decreases on repeat scintigraphy has been interpreted as a decrease in the zone of initial ischemia and consequently salvage of ischemic myocardium).[4,5] Optimal assessment of baseline or serial changes, or both, in myocardial perfusion in these different pathologic situations requires that the myocardial localization of an imaging agent be principally determined by regional myocardial perfusion and not by perturbations in cellular metabolism which may vary with different conditions of reduced blood flow.

From the Departments of Cardiology and Radiology, Duke University Medical Center and the Veterans Administration Medical Center, Durham, North Carolina. This work was supported in part by Research Grant HL 18537 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland, and the Medical Research Service of the Veterans Administration Medical Center, Durham, North Carolina. Manuscript received November 23, 1981; revised manuscript received April 12, 1982, accepted April 16, 1982.

Address for reprints: Frederick R. Cobb, MD, Division of Cardiology, Veterans Administration Medical Center, 508 Fulton Street, Durham, North Carolina 27705.

The objective of the present study was to compare the myocardial localization of thallium-201 with direct measurements of myocardial perfusion by inert nondiffusable microspheres in normal, acutely ischemic, and recently infarcted myocardium. These interventions were selected to simulate the different conditions of reduced blood flow and potentially different local myocardial metabolic influences that may be encountered in the clinical use of this isotope.

Methods

Experimental preparation: Six mongrel dogs weighing 15 to 25 kg were anesthetized intravenously with thiamylal sodium, 30 to 40 mg/kg body weight, and ventilated with a respirator. A left thoractomy was performed in the fourth intercostal space. The circumflex coronary artery was dissected free just proximal to the first marginal branch, and the left anterior descending coronary artery was dissected free just distal to the first diagonal branch. An adjustable occluder was loosely positioned around each vessel and stabilized to the fibrous tissue adjacent to the vessel bed. Polyvinyl chloride catheters (outer diameter, 3 mm) were filled with heparin and inserted into the left atrium through the left atrial appendage and in the ascending aorta through the left internal thoracic artery. The occluders and catheters were tunneled to separate subcutaneous pouches at the base of the neck. The dogs were then allowed to recover from the surgical procedure.

Seven to 10 days after recovery from the surgical procedure, each dog was sedated with 0.3 to 0.4 mg/kg of morphine sulfate intramuscularly and the circumflex occluder was exteriorized from the subcutaneous pouch after lidocaine infiltration anesthesia. The circumflex coronary artery was per-

manently occluded. Lidocaine, 2 mg/kg, and morphine sulfate, 0.06 to 0.08 mg/kg, were administered intravenously to reduce arrhythmias and to minimize discomfort. The electrocardiogram was monitored before and after occlusion; proper function of the occluder was verified by elevation of S-T segments and an increase in heart rate after occlusion, and the presence of ventricular arrhythmias 24 hours after occlusion. The dogs were then allowed to recover from the occlusion.

Thallium-201 and microsphere injection: Three to 4 days after infarction, each dog was again sedated with 0.3 to 0.4 mg/kg of morphine sulfate intramuscularly. The pouches were infiltrated with lidocaine and the catheters and the left anterior descending occluder were exteriorized. Each dog was given lidocaine and morphine sulfate intravenously. Blood flow was measured using 9 ± 1 μm scandium[46]-labelled microspheres before occlusion to ensure that premature closure of the snare had not occurred and that acute ischemia was subsequently initiated. The left anterior descending coronary artery was then completely occluded. One minute after complete occlusion, thallium-201, 0.5 mCi, was injected into the left atrium; niobium[95]-labelled microspheres were injected into the left atrium immediately after the thallium-201 injection. Serial blood samples were withdrawn from the aortic catheter as previously described[6,7] for calculation of regional blood flow. The occlusion was maintained and 5 minutes after injection of thallium-201 each animal was anesthetized rapidly with 40 mg/kg of thiamylal sodium; the heart was fibrillated with potassium chloride solution and immediately extracted and cooled to approximately 5 to 10°C.

Tissue samples for comparing blood flow and thallium distribution: The heart was immediately prepared for sectioning. The right ventricle, atria, aorta, and pericardial fat were removed. The left ventricle was sectioned into 4 transverse layers of approximately equal thickness (Fig. 1); the apical ring was sectioned into 1 anterior and 1 or 2 posterior regions; the other rings were sectioned into anterior, anterior papillary, lateral, posterior papillary, posterior, and septal regions. Each apical region was further sectioned into 3 transmural layers of approximately equal thickness, whereas each of the other regions was sectioned into 4 transmural layers. This procedure generated approximately 80 tissue samples, weighing 0.7 to 2.0 g, for comparison of blood flow and thallium distribution. The samples were placed in scintillation vials containing formalin for subsequent histologic processing.

Thallium-201 activity in the tissue sample in each vial was counted with a gamma spectrometer with a 54-100 keV window. The tissue samples and reference blood samples were then recounted for niobium[95] and scandium[46] activity at optimal window settings. Background activity and spillover activity were corrected by an appropriate computer program. Flow to each myocardial region was calculated using the following standard formula: $Q_m = Q_r \times C_m/C_r$, where Q_m = myocardial blood flow (ml/min), Q_r = reference blood flow (ml/min), C_m = count activity in the myocardium, and C_r = count activity in the reference blood samples. Myocardial blood flow for each sample was expressed as ml/min per g. Thallium-201 activity was expressed as counts/min per g. The relation of regional myocardial blood flow and thallium-201 distribution was analyzed by linear regression analyses.

Histology: After measurement of tissue radioactivity, the samples were prepared for histologic sectioning as described previously.[7] Each tissue sample was sectioned serially with a microtome and 4 histologic sections were taken from different depths through each small sample and stained with hematoxylin and eosin. Myocardial infarction was defined as inflammatory cell infiltrate, loss of normal cell architecture, and cellular dissolution. The extent of infarcted myocardium in each sample was determined with planimetry of histologic infarction in each section using a projection microscope and ultrasonic graph pen.[7]

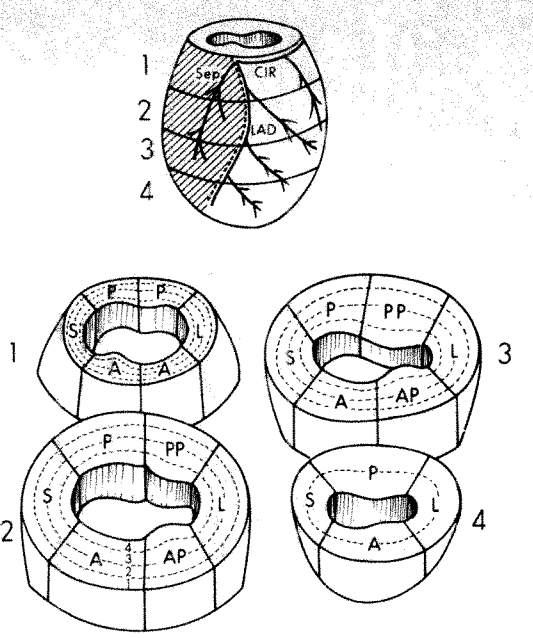

FIGURE 1. Diagram illustrating the technique for sectioning the left ventricle. The atrial tissue and right ventricle were removed as indicated by the **stippled** and **lined areas.** The left ventricle was sectioned into 4 transverse rings. Each ring was sectioned into circumferential regions: anterior (A), septal (S), posterior (P), posterior papillary (PP), lateral (L), and anterior papillary (AP). Each circumferential region in rings 1, 2, and 3 was divided into 4 equal epicardial and endocardial layers.

Results

Figure 2 illustrates the relation between the regional distribution of thallium-201 and myocardial blood flow as measured by 9 ± 1 μm microspheres. Data from all samples are plotted in each dog. In each dog there were myocardial regions in which blood flow was reduced less than 0.10 ml/min per g as a result of acute ischemia as well as of the infarction, initiated 3 days earlier. These data demonstrate a very close linear relation between thallium-201 localization and regional myocardial blood flow; *r* values were 0.98 or more in each dog. Thus the initial net localization of thallium-201 in acutely ischemic and recently infarcted myocardium as a function of regional blood flow was essentially identical. The *y* intercepts of each regression equation were slightly above zero. The slight scatter in data points was no greater at low as compared with normal flow ranges. The close linear relation and intercepts that approach zero indicate that net initial localization of thallium-201 closely approximates regional myocardial perfusion over a wide range of blood flow in acutely ischemic and recently infarcted myocardium. The differences in slopes resulted from differences in animal weights.

Proximal circumflex arterial occlusion resulted in an average infarct of 28.8% of the left ventricle (range 24 to 35%). The infarction extended to a variable degree of the epicardial surface. In the larger infarcts, infarction in the central ischemic regions extended to the epicardial surface.

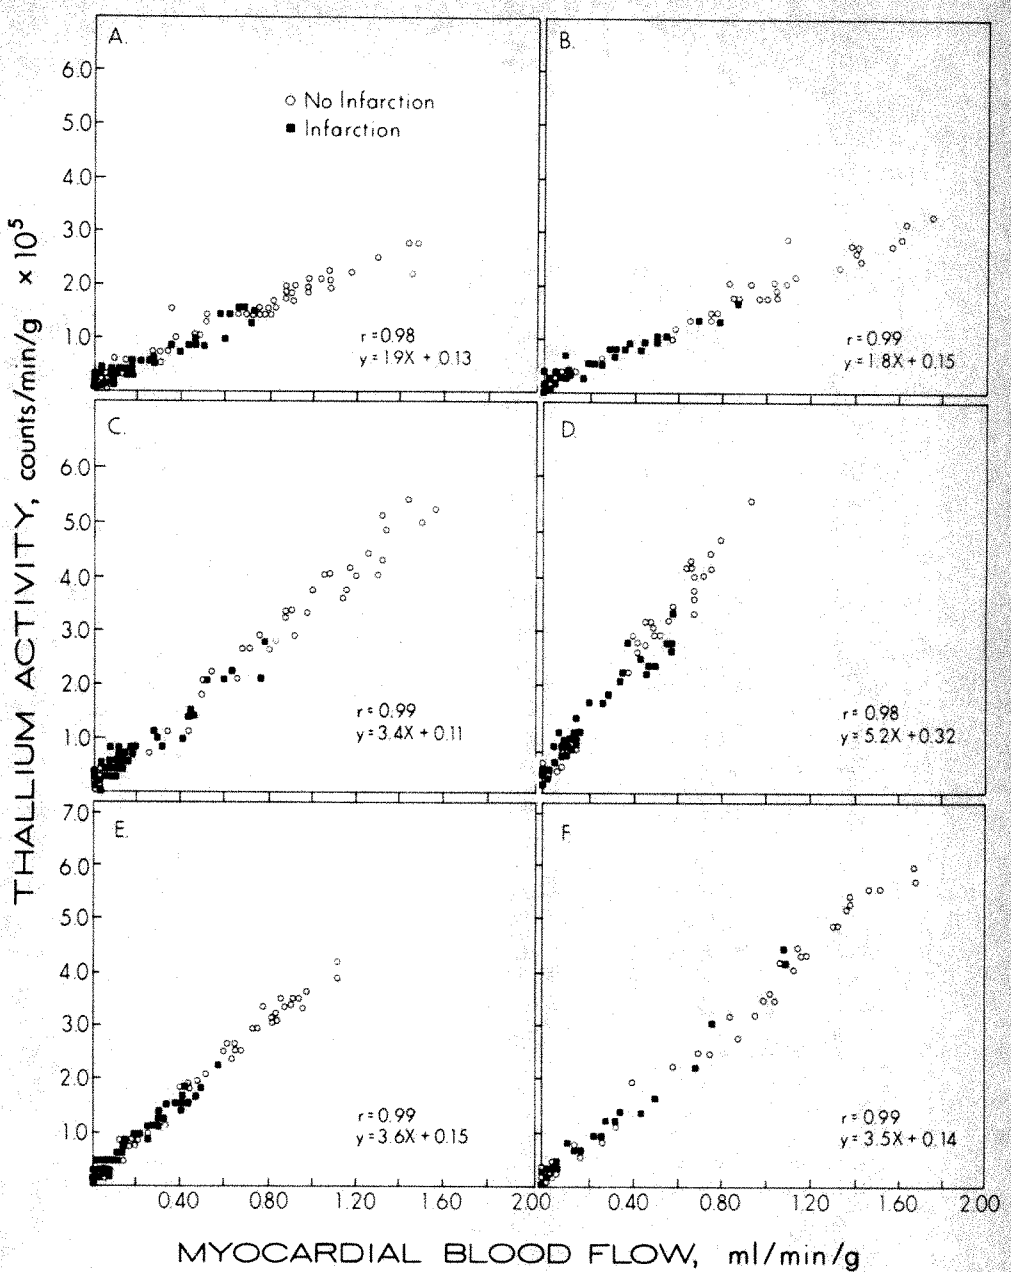

FIGURE 2. Relation between thallium-201 activity and myocardial blood flow in 6 dogs. **Closed squares** represent samples with greater than 5% histologic infarction.

Discussion

Possible limitation of thallium-201 for assessing myocardial perfusion during acute ischemia: Optimal scintigraphic assessment of myocardial perfusion in the clinical situations associated with coronary heart disease requires that myocardial localization of the imaging agent be a direct function of tissue perfusion over a wide range of reduced and increased blood flow, and variable local metabolic condition. Studies have suggested that the biologically active tracer ions such as potassium, rubidium, and thallium, which are extracted by the myocardial cell, have certain limitations as agents for accurately assessing myocardial perfusion during the variable metabolic conditions that may accompany acute or prolonged ischemia or evolving myocardial infarction, or both. Weich et al.[8] observed that the extraction fraction of thallium-201 remained constant when myocardial blood flow was altered by changing myocardial metabolic demands, but decreased when blood flow was increased in excess of metabolic demands or during systemic hypoxia or acidosis. Becker et al.[9] found a disproportionately high rubidium-86 content at very low flow rates as compared with measurements with nondiffusable inert microspheres. DiCola et al.[10] reported a close linear correlation between the distribution of thallium-201 and blood flow measured with microspheres in transmural myocardial sections 24 hours after coronary arterial occlusion. However, when the transmural samples were divided into epicardial and endocardial halves, there was a poor correlation between thallium-201 and microsphere distribution in the latter samples. The poor correlation in endocardial samples results from disproportionately

high thallium activity when blood flow was reduced less than 30% of normal.

Strauss et al.[11] reported a close linear correlation between regional blood flow determined with microspheres and thallium-201 distribution after acute coronary occlusion; thallium-201 underestimated blood flow when measurements were made during the reactive hyperemic phase after transient ischemia. In studies from our laboratory,[12] the regional distribution of thallium-201 and myocardial blood flow by microspheres was determined in dogs subjected to treadmill exercise and acute ischemia. We observed a very close linear correlation between thallium-201 localization and regional blood flow over a wide range of blood flow; in each dog blood flow was reduced to less than 0.1 ml/g per min in the ischemic region and increased 3.3 to 7.2 times resting blood flow in the nonischemic region; linear correlation coefficients were 0.98 or more in each dog.

Thallium-201 distribution in normal, ischemic, and infarcted myocardium: The purpose of the present study was to compare the initial myocardial localization of thallium-201 with simultaneous direct measurements of myocardial perfusion in normal, acutely ischemic, and recently infarcted myocardium. These conditions were chosen to simulate the potentially different pathologic conditions of reduced flow that may be encountered in the clinical use of thallium-201. Three to 4 days after initiation of infarction in the circumflex region, acute ischemia was produced in regions of the left anterior descending coronary artery. The 3 to 4 day period after acute myocardial infarction was selected to allow completion of the acute infarction process; at this interval the region subjected to prolonged ischemia was sharply delineated into infarcted and noninfarcted myocardium. The noninfarcted tissue was indistinguishable by routine histologic stains from tissue that had not been subjected to ischemia. Because substantial increases in collateral flow occur in the early days after acute coronary occlusion[13] the myocardium, which has been subjected to prolonged ischemia but which has not developed infarction, may no longer be subjected to ischemia. Thus, in samples with a mixture of normal and infarcted tissue it was not possible in the present study to determine whether blood flow to the normal tissue was normal or reduced. Although local metabolic conditions were not measured in the present study, it is possible that metabolic conditions of myocardial cells that have been subjected to no ischemia, acute ischemia, or prolonged ischemia but no infarction are different.

The results of our study demonstrate essentially identical localization of thallium-201 in these different regions when compared with direct measurements of blood flow by nondiffusable inert microspheres. These data indicate that regional myocardial perfusion is the principal determinant of initial localization of thallium-201 in each of the zones studied. Because the linear correlation coefficients approximated 1.0 and the intercepts of the regression equation were only slightly above zero in each dog, the data indicate that localization of thallium-201 very closely approximated regional perfusion over the entire range of myocardial blood flow. These data suggest that, compared with regional blood flow, the local metabolic conditions that may differ in normal and acutely ischemic myocardium and in regions containing recently infarcted myocardial tissue have inconsequential effects on initial thallium localization.

In the present study the animals were killed 5 minutes after thallium-201 and microsphere injection. Schwartz et al.[14] reported that the myocardial extraction of thallium-201 may become negative approximately 10 minutes after injection, suggesting early loss of the ion from the normal myocardium. Schwartz,[14] Pohost,[15] and their co-workers described early redistribution of thallium-201 to the ischemic region early after relief of ischemia. Thus, although the initial localization of thallium-201 may be closely related to regional perfusion over a wide range of blood flow and differing metabolic conditions, distribution at later intervals may not accurately reflect perfusion in either normal or ischemic myocardium or regions containing infarcted myocardium. These studies emphasize the need for early thallium scintigraphy after intravenous injection for optimal assessment of regional myocardial perfusion.

Jacob Mendez DaCosta: Medical Teacher, Clinician, and Clinical Investigator

CHARLES F. WOOLEY, MD

J. M. DaCosta, a scholarly, well-trained and observant clinician, was recognized during his lifetime as a well-known authority on physical diagnosis and had an unexcelled reputation as a clinical teacher. Chairman of Medicine at the Jefferson Medical College for 19 years, president of the College of Physicians of Philadelphia in 1884 and again in 1895, he was one of the original members of the Association of American Physicians and its president in 1897. Earlier in his career, his extensive Civil War study of "a form of cardiac malady common among soldiers . . . the study of which is equally interesting to the civil practitioner" was described in his 1871 paper "On Irritable Heart; A Clinical Study of a Form of Functional Cardiac Disorder and Its Consequences." Soon labeled *DaCosta's syndrome*, the irritable heart lineage can be traced through the *soldier's heart*, the *effort syndrome*, and *neurocirculatory asthenia* in World War I, *anxiety neurosis* in World War II, and the *mitral valve prolapse syndrome* in the second half of the 20th century.

The *Jefferson Medical College Alumni Bulletin* (spring 1975) contains an article by Robert I. Wise[1] which traces the history of the Chair of Medicine at Jefferson from its origins with the founding of Jefferson Medical College on June 2, 1824, when 4 physicians were appointed by the trustees of Jefferson College of Canonsburg (now the Washington and Jefferson College) as the first faculty of the new medical college. Joseph Klapp (1 year), John Eberle (5 years), Daniel Drake (1 year), John Revere (10 years), John Kearsley Mitchell (17 years), Samuel Dickson (14 years), Jacob DaCosta (19 years), and James C. Wilson (20 years) occupied the Chair of Medicine from 1824 to 1911, the period pertinent to my quest.

The early years: Jacob M. DaCosta entered Jefferson Medical College in 1849, graduated 3 years later at the age of 19 at a time when the medical faculty included John Kearsley Mitchell (medicine), T. D. Mütter (surgery), Charles D. Meigs (obstetrics), Franklin Bache (chemistry), Robley Dunglison, Joseph Pancoast (anatomy), and Robert Huston (dean of faculty, materia medica), during a "golden age, a time of distinction and academic prosperity for Jefferson."[1]

DaCosta brought an unusual background to medical college, at a time when the educational background of many American medical students was limited or nil. He was born on the island of St. Thomas, West Indies, in a family of Spanish and Portuguese extraction. His father, John Mendez DaCosta, a gentleman of wealth and culture, descended from an English branch of the family. Jacob was 4 when his parents left St. Thomas to live in Europe, where he and his brother Charles attended a gymnasium in Dresden. Studies included the classics and modern languages, and he became fluent in French and German, with a reading knowledge of Spanish, Portuguese, Italian and Dutch. He came to Philadelphia in 1849, where his mother was then living, and entered Jefferson Medical College.

As a student of Professor Mütter, DaCosta, along with friend and fellow student John H. Brinton, conducted demonstrations of tumors and specimens removed by Mütter at his clinics. Brinton, a Philadelphian, graduated with DaCosta in 1853, later served with Grant in the Tennessee and Cumberland River Campaign in 1862, and became Professor of Surgery at Jefferson after Samuel Gross in 1882. DaCosta married Frederica Brinton in April 1860.

After graduation, DaCosta spent 18 months in Paris and Vienna, involved in the study of pathology and internal medicine. Participation in medical and cultural

From the Department of Medicine, Ohio State University College of Medicine, Columbus, Ohio. Manuscript received February 1, 1982; revised manuscript received April 19, 1982, accepted April 26, 1982.

activities was enhanced by his knowledge of languages. He studied, attended the clinics, went to the great hospitals of Paris (Hotel Dieu, La Charité), and absorbed the wisdom of a great medical center where Robin, Claude Bernard, Verneuil, Néalton, Broca, and Trousseau were active and teaching. Trousseau, in particular, made a deep and lasting impression on the young DaCosta. Trousseau's magnificent lecture[2] on percussion began with a discussion of Auenbrueger, made the transition to Corvisart and his pupil Laennec, and traced the development of the physical examination of the chest as related to the concomitant development of urinalysis, examination by the speculum, the laryngoscope, and the opthalmoscope so "the most inaccessible organs can now be seen." Trousseau concluded with a reflection and a charge: "Rich in the possessions bequeathed to you by the physicians of the past, to you belongs the duty of uniting modern science with ancient wisdom, and of rekindling the temporarily despised torch of old medical traditions. Let this be your endeavor! It is a great and splendid aim! Fail not to pursue it!"

The impact of the Parisian teachers, and the further experiences in Prague and Vienna with August Klaatsch, Hyrtl, Skoda, Oppolzer, Bamberger, Rokitansky, and Hebra set, as Wilson[3] notes "... a clear course toward his lifework—pathological anatomy, visceral disease, the heart and lungs, and the diseases of the skin in their relation to general medicine; in a word, internal medicine in its broadest sense, the greatest of the specialties." Again, from Wilson: "He would be a teacher; at all events, he would fit himself to be one. The talent was inborn."

DaCosta returned to Philadelphia in 1853. Philadelphia, with a long tradition of leadership in American medicine, was the site of the nation's first medical school, hospital, school of pharmacy, and mental hospital. Baltzell[4] notes that in "... 1847, when the American Medical Association was founded in Philadelphia to bring order out of the chaos of standards then regulating the profession, all the officers either were practicing in the city or were graduates of the Penn Medical School; eight of the first ten presidents of the AMA trained at Penn." When DaCosta returned to this environment, he was invited to take part in the Summer Association for Medical Instruction located on Chant Street, "a place of historical interest in the medical life of Philadelphia, long famous for all kinds of extramural teaching. In this work he was associated with men somewhat older than himself, but still young, who had attracted attention as teachers and practitioners. Prominent among them were John Forsyth Meigs, Frank West, the Wallace brothers, Robert Bridges, John H. Brinton, and Addinell Hewson. To DaCosta was assigned the subject of Physical Diagnosis."[3]

DaCosta combined office practice (at 212 South Eleventh Street), instruction of students in physical diagnosis, and an appointment as a physician to the dispensary attached to the Moyamensing House of Industry.

The death of John Kearsley Mitchell in 1858 was followed by the appointment of Samuel Dickson to the Chair of Medicine at Jefferson. Dickson, trained under Physick, Dorsey, and Chapman at the University of Pennsylvania, had been one of the founders of the Medical College of South Carolina. "From this date DaCosta became closely identified with the Jefferson College, at first as an instructor of telling influence in connection with the Chair of Medicine, subsequently as clinical lecturer, and finally, in 1872, as the successor to Professor Dickson in the Chair of Practice."[3]

The Turner's Lane years: DaCosta's syndrome: The War Between the States affected Philadelphia in a unique way. Philadelphia became a major hospital center as the war progressed, and by 1865 there were 27 hospitals and 25,000 beds in or near the city. S. Weir Mitchell, son of John Kearsley Mitchell, recalled[5] that it "... became necessary to provide additional help in the hospital service, and this was supplied by employing what were known as acting assistant surgeons. They served at home, but were liable to be called into duty in the field. Except in the case of Antietam and Gettysburg this was rare. Among these were Agnew, Gross, Morton, Stillé, DaCosta, Harry Hart and many more."[5] A number of specialized infirmaries developed as the war progressed; one of these was designated by the U.S. Army Medical Department as the U.S. Army Hospital for Injuries and Diseases of the Nervous System, Turner's Lane. Weir Mitchell described the move from the building known as Moyamensing Hall on Christian Street to the Turner's Lane Hospital: "... the space proving insufficient, a surburban estate on Turner's Lane was rented in August 1862, and pavilions built for

400 men. One was assigned to DaCosta, and afforded him a chance for a classical study of exhausted hearts and for other able papers."[5]

The Turner's Lane story has been told by William Middleton[6] in a remarkable work. The contributions of S. Weir Mitchell, William Keen, and George Morehouse to clinical neurology represent an early example of the specialty approach in clinical medicine, with clinical research conducted in a controlled clinical research center. The earlier publication and recognition of these neurologic studies eclipsed the work by DaCosta from the same institution; although DaCosta presented preliminary reports of his work in 1862 and 1864, there was a long lag time from the original studies on soldiers with "irritable heart" to the publication of his definitive work in 1871.

The definitive report "On Irritable Heart: A Clinical Study of a Form of Functional Cardiac Disorder and Its Consequences"[7] is a landmark study in the history of cardiovascular disease. Jarcho[8] noted that in an era dominated by the search for organic ailments, "DaCosta's study of the condition which he named irritable heart was an attempt to cross the frontier into the obscure realm of functional disease. . . . DaCosta's paper is an impressive example of nineteenth century clinical research, conducted entirely by simple methods of history taking and physical examination without the assistance of the laboratory. The author was aided by a wise policy of the War Department, which concentrated cases of irritable heart in the hospital at Turner's Lane at Philadelphia under DaCosta's care. This favored the rapid accumulation of data and the synthesis of the clinical picture. A similar method had been in use in the hospitals of Paris and was extremely helpful if not essential to the work of Laennec and his great contemporaries."[8]

The report is a mature work by a young clinician who made good use of his knowledge of physical diagnosis, recorded and trusted his own carefully documented clinical observations, and filtered the essentials from studies of over 300 cases. After careful reflection he set forth a classic description of a clinical subject that would resurface periodically and be renamed *DaCosta's syndrome*, *soldier's heart*, *effort syndrome*, and *neurocirculatory asthenia* in World War I, *anxiety neurosis* in World War II, and the *systolic click-late systolic murmur syndrome* or the *mitral valve prolapse syndrome* in the 1960s and 1970s.[9]

DaCosta: clinical teacher: His medical treatise, "Medical Diagnosis," was published in 1864; it went through 9 editions, was intended as a guide to the knowledge and discrimination of diseases, and later appeared in German, Russian, and French translations. The approach that DaCosta used was to group morbid states "according to their marked symptoms."

DaCosta (Figure 1) was one of the founders of the successful and influential Pathological Society of Philadelphia, served as its secretary during the early years and as its president in 1864 through 1866. His early medical reports reflected his interest in pathology, and dealt with the pathologic anatomy of acute pneumonia and pancreatic cancer. He was 39 years old when he succeeded Dickson in the Chair of Practice; Wilson[3] noted that he had ". . . established himself as a successful practitioner, a teacher of the highest order, and a trusted consultant. . . . He served as physician to the Episcopal Hospital, to the Philadelphia Hospital, and to the Hospital of the Jefferson College, and was for many years consulting physician to the Childrens Hospital. . . . His clinics were models of the finest methods of medical instruction—clear, systematic, and impressive."

As a member of the staff of the Pennsylvania Hospital from 1865 until his death 35 years later, he exerted a "most important influence . . . upon the long line of resident physicians whose good fortune it was to serve with him."[3] Wilson himself was one of the physicians influenced by DaCosta, served as Chief Clinical Assistant to Professor DaCosta at Jefferson, and was appointed to Chair of Medicine when DaCosta resigned in 1891.

The historical archives at the Jefferson Library contain a "report of clinical lectures of Jacob M. DaCosta, M.D." for 1875, 354 pages of beautifully handwritten notes by Theodore Horwitz[10] submitted for the Professor DaCosta prize, which dealt with a broad spectrum of disease organized as to presentation, findings, diagnosis, and treatment. Reading through the Horwitz lecture notes and a later set by W. Wehner from 1884 to 1886, one is transported in time to DaCosta's Clinics, to eavesdrop on the professor and reflect on medical thinking of the time.

The manuscript of the valedictory address to the graduating class of the Jefferson Medical College of Philadelphia of 1891, "Professional Aspirations," contains a letter dated September 29, 1891: "My Dear Charlie, You asked me to give you the manuscript of something I have written. I give you this—my valedictory, and the last thing I wrote before resigning my Professorship. Ever affectionately, your father, J. M. DaCosta."[11]

As I reviewed the remnants of DaCosta's career, visited the archives at the College of Physicians of Philadelphia and at Thomas Jefferson University, I wondered why he is little known and honored within and without Philadelphia. After all, DaCosta, ". . . in the opinion of F. H. Garrison was probably the most able teacher of his time in the Eastern states,"[8] and Stone observed that he was ". . . perhaps the best know authority on physical diagnosis in this country, and for the past thirty years has had an unexcelled reputation as a clinical teacher."[12] He did not move once he was established at Jefferson, nor did he write a great deal, and these may be the important factors. The significance and originality of his Civil War researches have yet to be fully appreciated. He did not have the benefit of strong public relations (such as exists at Harvard, Hopkins, or the Rockefeller) during his lifetime or during this century. The class structure and cultural atmosphere of Philadelphia, as articulated by Baltzell,[4]

wherein the Quaker traits of modest behavior and gentlemanly decorum interfere with the assumption of dominant leadership roles, deserve serious consideration. The replacement of the master clinician-teacher in the medical heirarchy by the scientific researcher, coupled with gradual erosion of Philadelphia's early medical leadership role, must rank as contributing factors.

Mary A. Clarke,[13] for many years DaCosta's private secretary, wrote a richly detailed memoir which appeared in the *American Journal of Medical Science* in 1903, and supports Baltzell's Philadelphia Gentleman's hypothesis: "Dr. DaCosta was greatly opposed to the publications of biographical sketches of the living, and invariably refused to give information concerning himself for such projected works. Only after Harvard had conferred upon him, in 1897, the degree of L.L.D., and at the urgent request of the editors of the *Harvard Graduates' Magazine*, he furnished them a brief sketch of his life, which has been made use of by other journals."

Although reticent about publication of details of his personal life, Wilson[3] tells us that DaCosta had "a deep interest in the welfare of the organized profession, an interest he maintained throughout his life." His leadership qualities were manifest as chairman of a major department at a major medical college for 19 years, in the College of Physicians of Philadelphia as a Fellow (1858) and its president in the line of Redman and Shippen in 1884 and 1855 and again a decade later from 1895 to 1898, and as one of the original members of the Association of American Physicians and its President in 1897.

It seems fitting to recall Jacob Mendez DaCosta for many reasons—as an early American clinical investigator working in a clinical research center (Turner's Lane), as a patron for unsung clinicians and teachers in medical schools, as an example of the finest qualities of the Philadelphia medical spirit, and as a noble man and physician. At a time when ambition and commercialism have confused the current medical leadership, hierarchy, and membership as to the essential roles and function of physicians, the simplicity, the directness of purpose, and the essential nobility of the man deserve recall and incorporation into our individual lives. It certainly seems reasonable to search for his qualities within ourselves and among all students of medicine.

Acknowledgment

The time, kindness, materials, and assistance extended to me by Robert T. Lentz, Archivist, and Samuel A. Davis, Librarian, Scott Memorial Library, Thomas Jefferson University, and Lisabeth M. Holloway, Christine Ruggere, and Pat Connors, Historical Collections, Library of the College of Physicians of Philadelphia, are gratefully acknowledged. Franklin Freeman, great-grandson of Dr. William W. Keen of Philadelphia and a student of Philadelphia Medicine, shared valuable insights, perspectives, and information. Jo Ann Martin provided secretarial assistance.

Hypothesis: Is Congestive Cardiomyopathy Caused By a Hyperreactive Myocardial Microcirculation (Microvascular Spasm)?

STEPHEN M. FACTOR, MD, and EDMUND H. SONNENBLICK, MD

In most congested, dilated cardiomyopathies, pathologic analysis reveals focal myocardial necrosis, microscopic scarring, interstitial fibrosis, and myocellular hypertrophy. The focal nature of these processes indicates that the cardiomyopathies may not be due to diffuse abnormalities of cardiac muscle cells, at least in the early stages, but that the changes may represent focal events affecting discrete, small volumes of tissue. Experimental evidence of microvascular hyperreactivity (spasm), both in the hereditary cardiomyopathy of the Syrian hamster and in the acquired cardiomyopathy of the hypertensive-diabetic rat, suggests that transient spasm of the myocardial microcirculation may lead to focal myocellular necrosis and scarring, which then causes the unaffected myocardial cells to undergo compensatory hypertrophy in order to normalize the increased load per unit of myocardium. When enough myocardium is lost and the compensatory hypertrophy results in decreased contractility, congestive heart failure ensues as a systemic response to altered ventricular function. The efficacy of verapamil therapy in the Syrian hamster in preventing microvascular spasm, cell necrosis, and the subsequent development of a cardiomyopathy has provided hope that similar preventive treatment can be applied to patients with early stages of cardiomyopathy.

Diminished or inadequate myocardial contractility is a common manifestation of congestive cardiomyopathy, which may lead to clinically apparent congestive heart failure with all of its attendant effects on the peripheral and pulmonary circulations. It is generally believed that ventricular dysfunction in most cardiomyopathies results from diffuse involvement of cardiac muscle cells, whether due to an idiopathic insult or due to damage induced by viral agents, disturbed metabolism, or toxins (such as alcohol).[1–3] Although hereditary metabolic diseases such as alpha-1,4 glucosidase deficiency (Pompe's type II glycogen storage disease) may, in fact, result in *diffuse* myocellular changes,[4] most congestive cardiomyopathies do not demonstrate homogeneous myocardial changes when evaluated histologically. Even experimental or clinical genetic diseases primarily affecting skeletal and cardiac muscle (such as Syrian hamster cardiomyopathy and Duchenne's muscular dystrophy) typically manifest *focal* myocardial lesions.[5–7] Thus the explanation for abnormal myocardial contractility often is not evident from morphologic analysis of cardiac tissue in these diseases.

Pathologic Features of Congestive Cardiomyopathy

The pathologic features[1–3,8–11] of most congested, dilated cardiomyopathies, whether primary or secondary, are nonspecific and cannot be employed to make a diagnosis of "heart muscle disease" without corresponding clinical or laboratory findings. Grossly, one sees a large, flabby, or firm heart with prominent ventricular dilatation. Microscopically, there may be all or a combination of the following changes: (1) interstitial fibrosis or edema surrounding individual or groups of seemingly viable myocardial cells; (2) loose or compact connective tissue encircling the microvasculature and the larger muscular vessels; (3) very discrete, sharply delimited zones of acute myocytolytic necrosis which

organizes into microscopic or confluent macroscopic scars; (4) intimal and medial sclerosis and hypertrophy of intramyocardial muscular vessels, often causing luminal compromise; and (5) varying degrees of myocellular hypertrophy. None of these features is characteristic solely of cardiomyopathy; they are frequently present in the hearts of patients with significant obstructive coronary artery disease.

Hypothesis

Because the changes just described are focal and nonspecific, most investigators have assumed that uninvolved myocardial cells are abnormal biochemically or functionally. Surprisingly little evidence has been accumulated to support this view. Abnormalities have been identified, but they are often insignificant, or more related to severe congestive heart failure than to the condition that led to that failure.[12] When care has been taken to select myocardium from uninvolved regions of cardiomyopathic hearts, analysis of ultrastructure generally reveals changes consistent with cellular hypertrophy, and biochemical or histochemical features are only slightly deviated from normal, if at all.[3,5,8,13–15] Nonselective techniques (blind biopsy sampling or tissue homogenization) often demonstrate significant changes such as increased lysosomal enzyme activity, changes in contractile proteins, and deranged mitochondrial and sarcoplasmic reticulum function.[5,16–18] Although such data are employed to support the concept of diffuse, homogeneous myocellular disease, in fact, they can also be considered to represent an admixture of heterogeneous normal and abnormal tissue.

We present herein an alternative hypothesis concerning the pathogenesis of at least some congestive cardiomyopathies, while recognizing that the mechanisms described may be generalized phenomena. We believe that the development of cardiomyopathy is related to progressive and additive *focal cellular necrosis*, and associated replacement myocardial fibrosis, and that these processes may in some cases be mediated by *dynamic alterations in the myocardial microcirculation*.[19–24] An abnormal microcirculation also could lead to the deposition of interstitial connective tissue around viable myocytes and blood vessels, which may limit diastolic compliance ("stiff heart") or interfere with cellular nutrition. Compensatory hypertrophy may be superimposed on these processes, but eventually progressive hypertrophy may be associated with decreased contractility.[25,26] When a threshold number of nonregenerating myocardial cells undergo necrosis or are affected by connective tissue deposition over time, a sufficient derangement of ventricular function may ensue which is clinically manifested as the syndrome of congestive heart failure. This is analogous to the abrupt loss of large volumes of tissue due to a myocardial infarction producing chronic failure or acute cardiogenic shock. However, the slow, relentless, and even subclinical nature of the cardiomyopathic process has obscured the similarities between the 2 conditions.

Models of Cardiomyopathy

We have identified dynamic microvascular alterations in several experimental cardiomyopathies.

The Syrian hamster,[5,7,24] a heritable model of muscular dystrophy and congestive cardiomyopathy, develops focal myocytolytic necrosis of the heart at approximately 30 days of age, which continues actively for 3 to 4 months with hypertrophy of uninvolved cells and results in congestive heart failure within the first year of life. Pathologic analysis of these hearts reveals discrete zones of focal ventricular necrosis and fibrocalcific scarring, with insignificant alterations in the unaffected myocytes. The pattern of necrosis, with *groups* of cells undergoing myocytolysis sharply delimited from surrounding normal myocardium, is consistent with mediation by the microvasculature. Myocytolysis is a form of muscle necrosis commonly associated with increased levels of or hypersensitivity to endogenous or exogenously administered catecholamines[27]; however, it may also be produced by transient occlusion of a coronary vessel followed by reperfusion.[28] Despite a possible relation to the coronary microvasculature, histologic and ultrastructural studies have revealed no fixed anatomic obstructive lesions in the microcirculation of these animals.

In an attempt to define a dynamic microcirculatory lesion, we perfused hamster hearts while they were beating with a silicone rubber solution (Microfil®) which completely fills the microcirculation and hardens in situ. By clearing the tissues, we observed a 3-dimensional array of small vessels down to the capillary level, analogous to a microangiogram, with the vessels visualized as in a stop-frame at the moment of death. In the cardiomyopathic animals, we frequently identified arterioles and capillaries with areas of focal narrowing consistent with spasm (Fig. 1), with no anatomic obstruction in these vessels.[20,24] Since the presence of a stenotic zone within a vessel lumen of normal caliber can be explained only by structural deformation of the vessel or contraction of its wall (spasm), we believe that the absence of disease in the vessel wall is evidence that the process is secondary to spasm. These focal, narrowed zones were extremely rare in the control hearts. The calcium blocking agent verapamil, which can prevent the development of necrosis in hamster hearts, also prevented the microvascular spasm, presumably because it is a potent smooth muscle relaxant and coronary vasodilator.[21,24] Thus, focal necrosis in these hearts, which is the major pathologic feature of the disease, may result from transient and focal spasm of the microcirculation supplying small groups of myocardial cells.

Although these observations suggest a possible pathogenetic mechanism in hamster cardiomyopathy, they must be viewed with caution. We do not claim that the microvascular spastic lesions identified with our methods are causally related to specific myocardial necrotic foci. Rather, it is likely that they indicate a general hyperreactivity of the microcirculation, possibly stimulated by the introduction of anesthesia, surgical manipulations, or Microfil perfusion. However, the

vascular changes do appear to be markers of a difference between cardiomyopathic and normal animals, because they were virtually absent in the controls. Furthermore, the lesions were prevented with verapamil therapy, implying that they were not artifactually induced. The effectiveness of verapamil in this regard suggests that it may act primarily on the microcirculation; however, we cannot rule out the possibility that the drug acts directly on the myocardial cells to prevent necrosis. Studies with vasodilators which do not interact with myocardial cells are necessary before definitive conclusions can be drawn about this disease.

A question crucial to the hypothesis is whether transient obstruction of the microcirculation can produce small areas of myocardial necrosis. This would require that the microcirculation be arranged as an end-vessel system; otherwise, intercapillary anastomoses could supply transiently ischemic cells with sufficient substrate to maintain viability. In fact, we have shown that the microcirculation is arranged into capillary loops without intercapillary connections in the dog[29] and recently in humans,[30] and we have reason to believe that a similar pattern exists in rodents (personal observations, 1981). We also have shown that embolization of 25 to 50 μm microspheres into the microcirculation of dogs or rats produces focal necrosis very similar to that seen in the hamster.[31] Variation in the size of the necrotic lesion may depend on the size of the vessel occluded, and could account for similar variability in clinical or experimental diseases. It is interesting that these microembolic phenomena appear secondary to vasospasm, as necrosis can be prevented with alpha-adrenergic blockade.

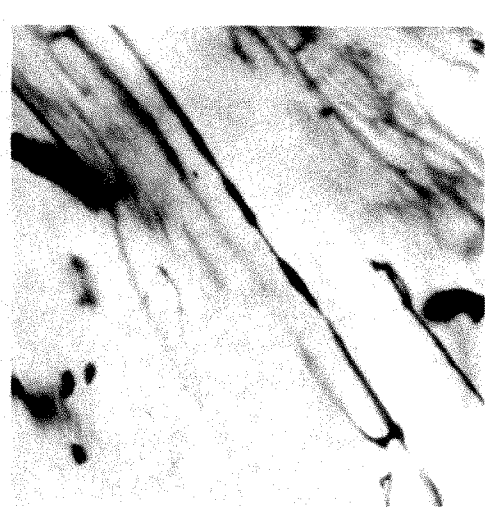

FIGURE 1. Silicone rubber (Microfil) perfused microcirculation in a 50 day old cardiomyopathic hamster, studied during the period of active myocardial necrosis. The precapillary vessel in the center of the field has several discrete areas of narrowing, with pre- and poststenotic dilatation of the lumen. Other studies of similar vessels have demonstrated no anatomic lesions associated with these narrowed zones, thus supporting the view that these stenoses are secondary to hyperreactivity or spasm of the vessel wall. (Transilluminated, cleared myocardium; magnified X150, reduced 19 percent.)

For the mechanisms suggested by our observations in the hamster to have applicability to other forms of heart muscle disease, additional models must be evaluated. In this regard, we have identified very similar features of myocytolytic necrosis, fibrosis, and cellular hypertrophy in an acquired cardiomyopathy initially described clinically and subsequently produced in animals.[10,11] Hypertensive-diabetic cardiomyopathy in both humans and rats is characterized by numerous foci of myocytolytic necrosis. In contrast to Syrian hamster cardiomyopathy, however, extensive interstitial connective tissue (collagen and basement membrane material) is also deposited around vessels and hypertrophied myocardial cells. In studies of the microcirculation in the rat model employing silicone rubber perfusions in vivo, a multiplicity of microvascular constrictions, tortuosities, and microaneurysms were identified.[19,22,23] These lesions, which appear consistent with microvascular spasm, may account for the extensive myocytolytic necrosis in these hearts. Interstitial fibrosis, however, may result from increased "leakiness" of the microcirculation secondary to the combined effects of hypertension elevating perfusion pressure and diabetes mellitus damaging the vessel wall. We do not know yet whether the morphologic changes in this disease can be prevented with vasodilator therapy, although this will be a crucial test of the hypothesis.

Conclusion

Lesions consistent with microvascular hyperreactivity (spasm) observed in several models of cardiomyopathy suggest that dynamic vessel obstruction may lead to the focal cell necrosis and subsequent fibrosis characteristic of these diseases. The similarity of these paradigms of human disease to other cardiomyopathies suggests that comparable microcirculatory events may be a feature of congestive cardiomyopathy in general. To test the hypothesis, additional studies of other cardiomyopathic models will be required to determine whether lesions can be identified in the microvasculature. The ultimate test will be whether such lesions can be prevented with the use of vasodilators which do not affect the myocardial cell, thereby preventing the development of cardiomyopathy. In addition, longitudinal studies in which multiple foci of micronecrosis are produced with microemboli or catecholamines will be important to determine whether summated myocardial insults can lead to cardiomyopathy. If the results of such studies are consistent with our preliminary observations, then the hypothesis presented herein may provide an insight into the pathogenesis of congestive cardiomyopathy and will serve to shift the focus in this condition away from the myocardium to the microcirculation. Rational therapy may thereby be advanced for this disorder in man.

Acknowledgment

We appreciate the invaluable assistance of Drs. T. Minase and S. Cho, and others too numerous to name who have contributed to these studies. We thank Marilyn Sasso for her excellent work in the preparation of this manuscript.

K-LYTE/CL®

Each effervescent tablet in solution supplies 25 mEq potassium chloride.

It's everything you need in a potassium supplement.

Mead Johnson PHARMACEUTICAL DIVISION

Double-strength K-Lyte/Cl® 50 also available. Each effervescent tablet in solution supplies 50 mEq potassium chloride.

© 1982 Mead Johnson & Company • Evansville, Indiana 47721 USA

Please see following page for summary of prescribing information.

K-Lyte/Cl® 50 (Each effervescent tablet in solution supplies 50 mEq potassium and chloride as supplied by potassium bicarbonate and L-lysine monohydrochloride.)
K-Lyte/Cl® (Each effervescent tablet in solution supplies 25 mEq potassium and chloride as supplied by potassium bicarbonate and L-lysine monohydrochloride.)

Description: K-Lyte/Cl 50 and K-Lyte/Cl are oral potassium and chloride supplements. Each K-Lyte/Cl 50 mEq tablet in solution provides 50 mEq of potassium and chloride as supplied by 2.24 gm of potassium chloride, 2.0 gm of potassium bicarbonate, and 3.65 gm of L-lysine monohydrochloride with 1.0 gm of citric acid, saccharin, natural and artificial flavor and artificial color. Each K-Lyte/Cl tablet in solution provides 25 mEq of potassium and chloride as supplied by 1.5 gm of potassium chloride, 0.5 gm of potassium bicarbonate and 0.91 gm of L-lysine monohydrochloride with 0.55 gm of citric acid, saccharin, natural and artificial flavor and artificial color.

Indications and Usage: All K-Lyte® products are used for therapy or prophylaxis of potassium deficiency. They are useful when thiazide diuretics, corticosteroids, or diarrhea cause excessive potassium loss; and when dietary potassium is low. These products may also be useful when potassium therapy is indicated in digitalis intoxication. K-Lyte/Cl 50 and K-Lyte/Cl are recommended in the management of hypokalemia accompanied by metabolic alkalosis and hypochloremia, e.g., as induced by vomiting.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal impairment, metabolic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns or adrenal insufficiency. Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Warnings: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and may be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Precautions: *General precautions* – The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. When interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Therefore, the treatment of potassium depletion requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the ECG, and the clinical status of the patient.
Information for patients – To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each dose completely in the stated amount of water.
Laboratory tests – Frequent clinical evaluation of the patient should include ECG and serum potassium determinations.
Drug interactions – The simultaneous administration of potassium supplements and a potassium-sparing diuretic can produce severe hyperkalemia (see Contraindications). Potassium supplements should be used cautiously in patients who are using salt substitutes because most of the latter contain substantial amounts of potassium. Such concomitant use could result in hyperkalemia.
Usage in pregnancy – Pregnancy Category C – Animal reproduction studies have not been conducted with any of the K-Lyte products. It is also not known whether these products can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. They should be given to a pregnant woman only if clearly needed.
Nursing mothers – Many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from oral potassium supplements, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.
Usage in children – Safety and effectiveness in children have not been established.

Adverse Reactions: The most common adverse reactions to oral potassium supplements are nausea, vomiting, diarrhea and abdominal discomfort. These side effects occur most frequently when the medication is not taken with food or is not diluted properly or dissolved completely.
Hyperkalemia occurs only rarely in patients with normal renal function receiving potassium supplements orally. Signs and symptoms of hyperkalemia are cardiac arrhythmias, mental confusion, unexplained anxiety, numbness or tingling in hands, feet or lips, shortness of breath or difficult breathing, unusual tiredness or weakness and weakness or heaviness of legs (see Contraindications, Warnings and Overdosage).

Dosage and Administration: *Adults* – One (1) K-Lyte/Cl 50 tablet (50 mEq potassium and chloride) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily, depending on the requirements of the patient. One (1) K-Lyte/Cl tablet (25 mEq potassium and chloride) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily, depending on the requirements of the patient.
Note: It is suggested that all K-Lyte products be taken with meals and sipped slowly over a 5 to 10 minute period.

How Supplied: K-Lyte/Cl® Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30, 100 and 250. K-Lyte®/Cl 50 Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30 and 100. Each tablet is individually foil wrapped.

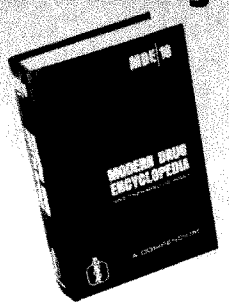
How thorough and unbiased is your drug reference?



If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

Currently available antianginal agents...
and how they are most appropriately employed as

BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

Synopsis of the Symposium

Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

Nitrates are basic in step-care therapy for ischemic heart disease

Step 1
Stable or unstable angina: Nitrates

Step 2
If not controlled: Nitrates + beta blockers

Step 3
If still not controlled (or in variant angina): Nitrates + calcium antagonists

The basic antianginal agent in these basic dosage forms

ISORDIL® SUBLINGUAL
Sublingual Tablets, 2.5 mg, 5 mg, and 10 mg

ISORDIL® CHEWABLE
Chewable Tablets, 10 mg

ISORDIL® TITRADOSE®†

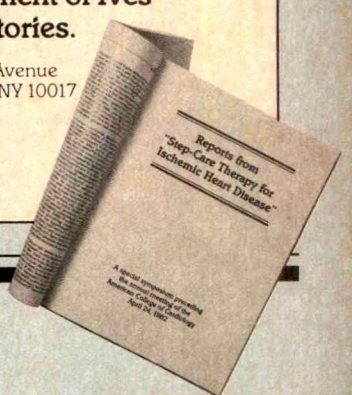
New York, NY 10017



In angina pectoris...

ISORDIL® (ISOSORBIDE DINITRATE)

is basic

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

© 1982 Ives Laboratories Inc.

ISORDIL®
(ISOSORBIDE DINITRATE) IS BASIC

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

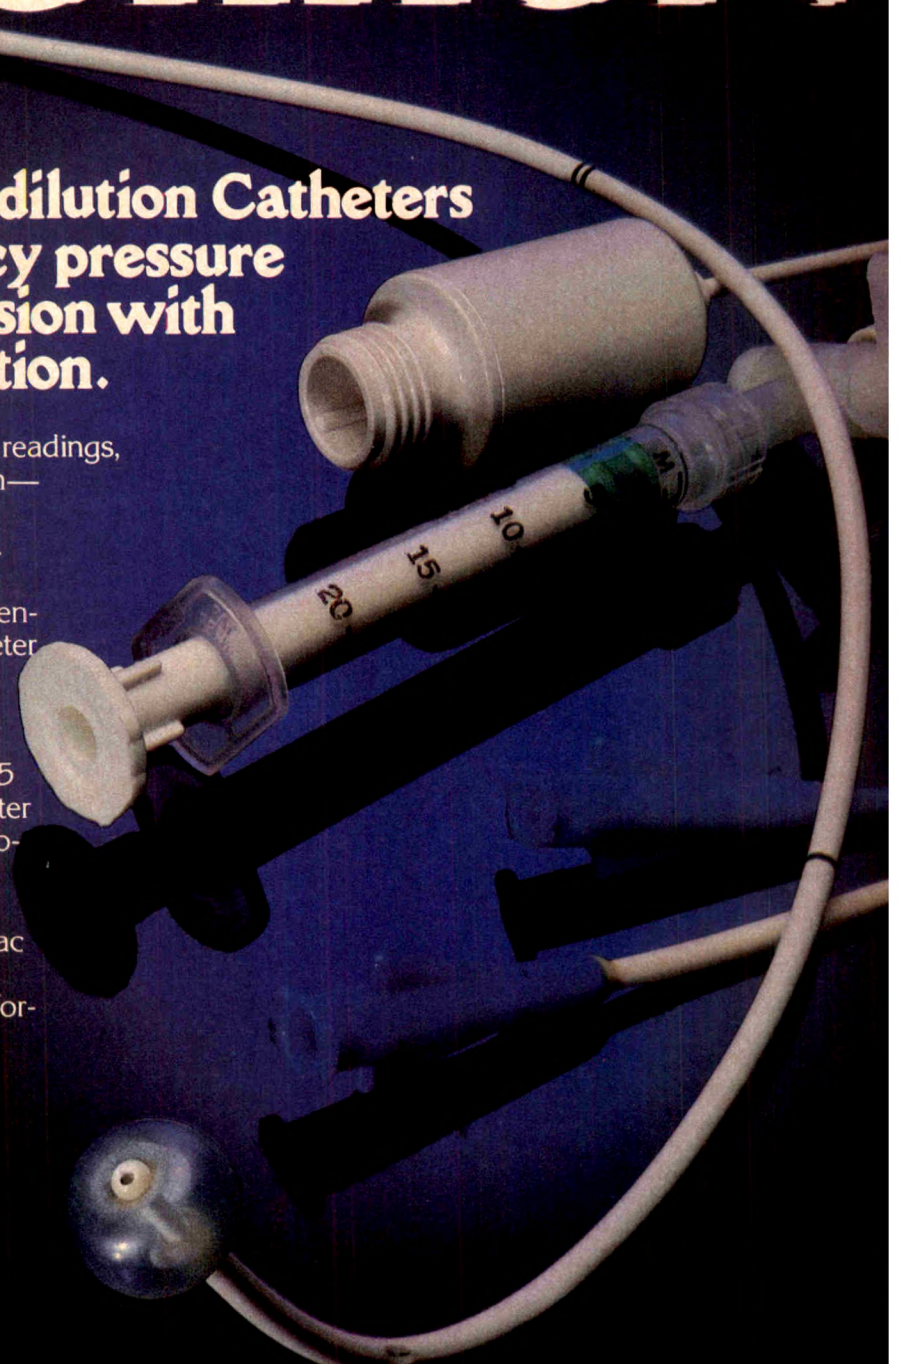
For clinicians who can't accept DISTORTION

CRITIKON Thermodilution Catheters deliver high accuracy pressure waveform transmission with special tip construction.

When you need intracardiac pressure readings, you want an accurate monitoring system—because your diagnosis cannot be more reliable than the data it is based on.

Thanks to the special tip design of the Critikon Thermodilution Catheter, the opening at the tip is the same size as the catheter lumen. That means pressure waveforms are transmitted with minimal distortion since there are no restrictions at the tip opening. The high resonant frequency, 25 Hz, of the Critikon Thermodilution Catheter ensures the faithful transmission of hemodynamic data.

See how the Critikon Thermodilution Catheter can deliver improved intracardiac pressure readings in your hospital. Ask your Critikon Representative for more information, or call us at 800-237-7541 (FL: 800-282-9151).

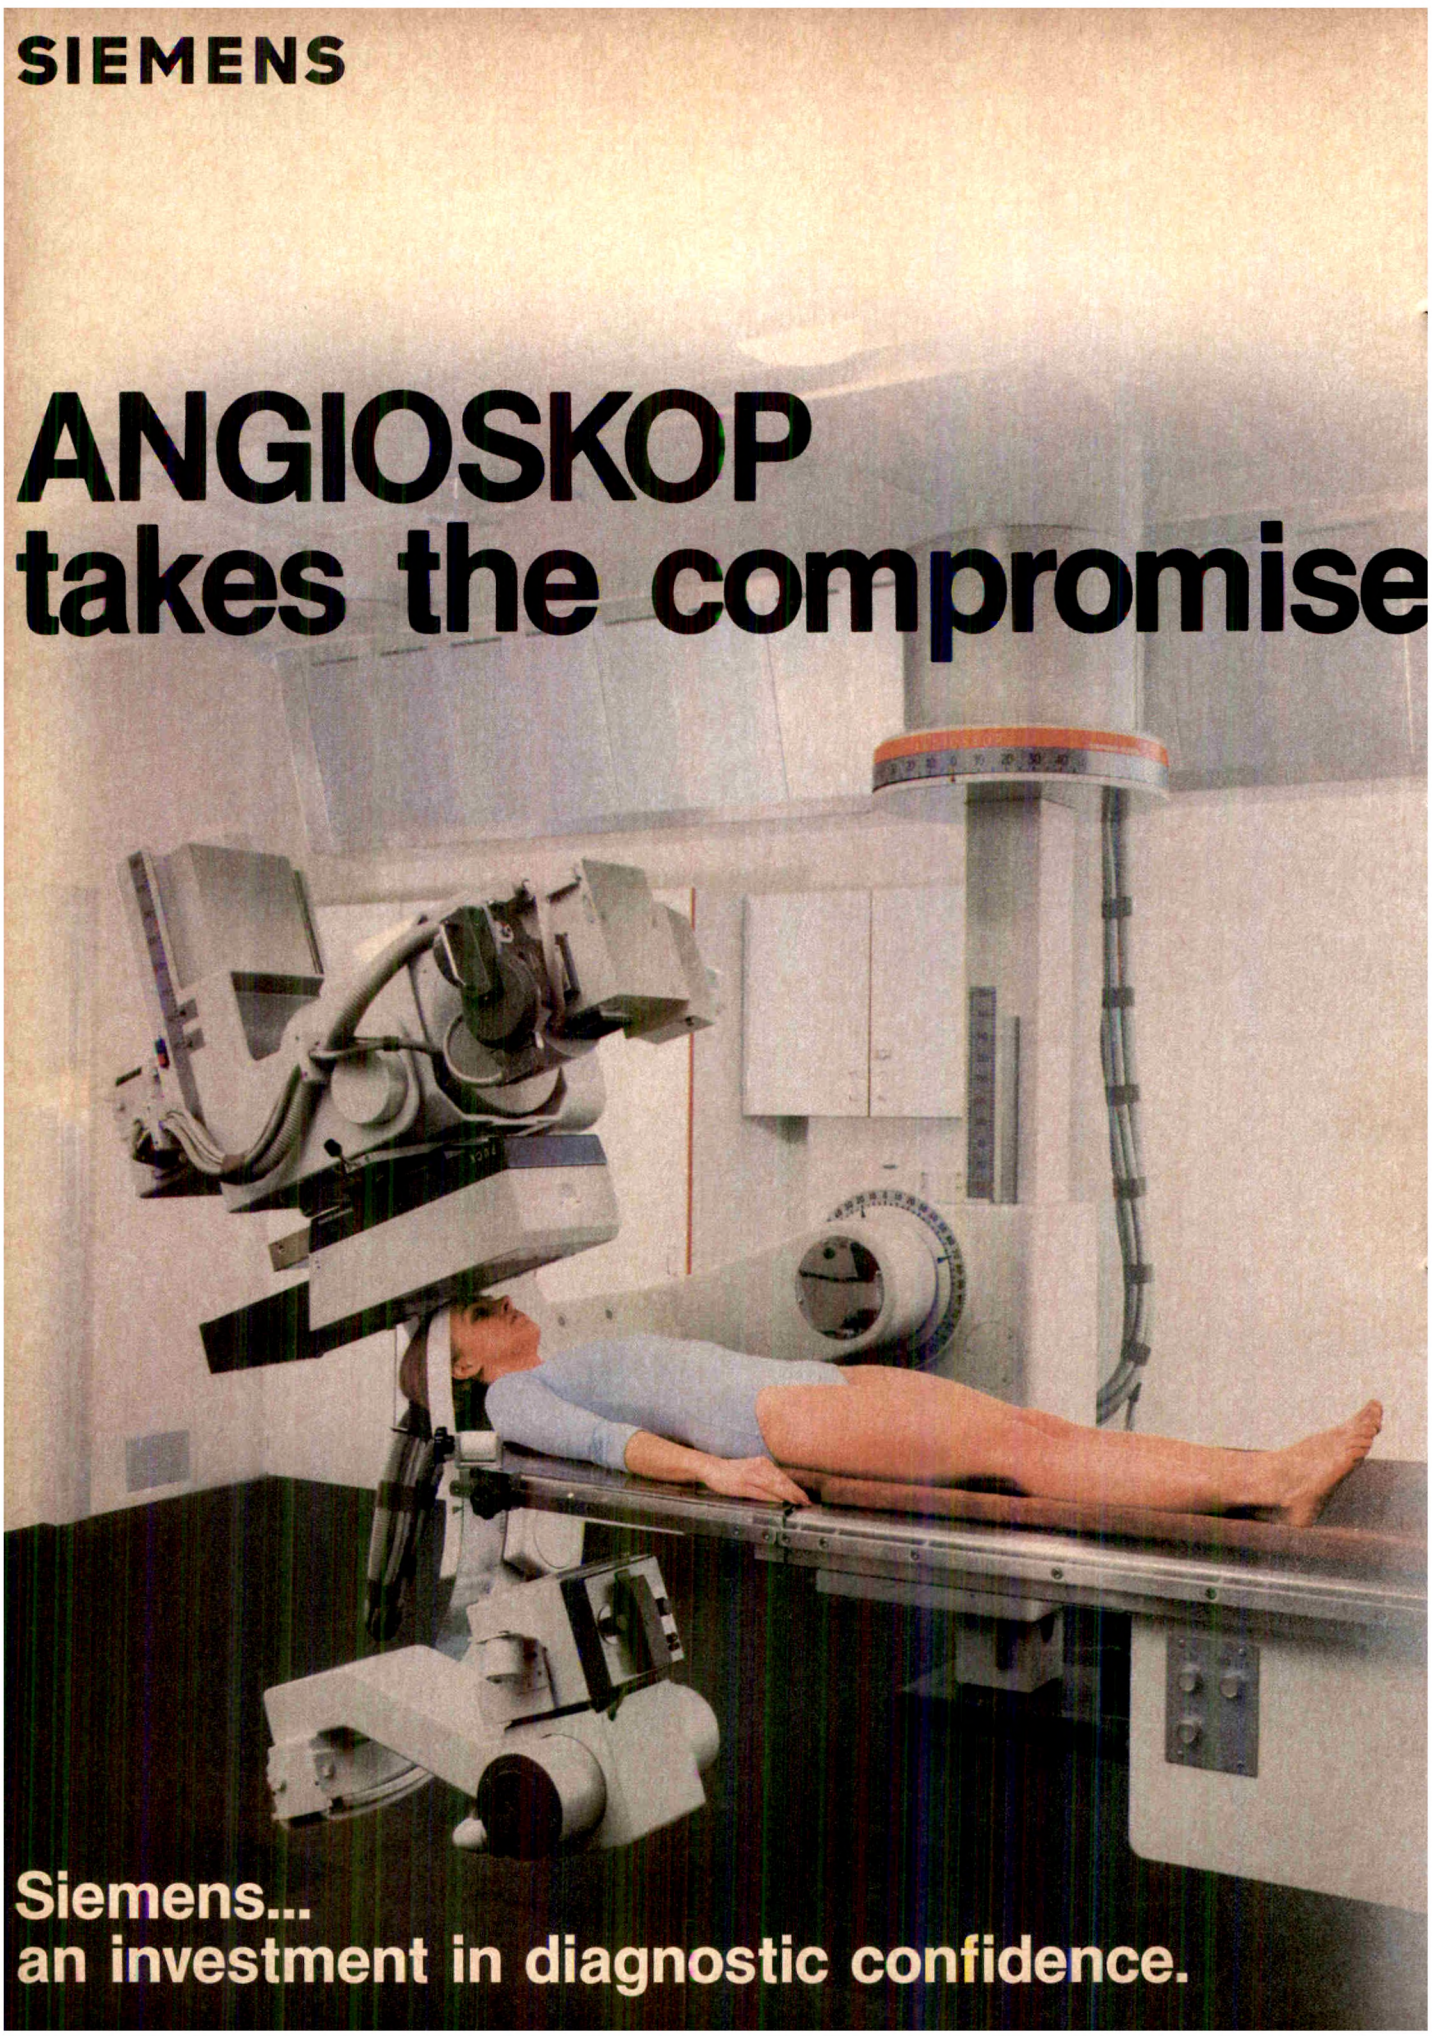


CRITIKON

The Critical Care Company

SIEMENS

ANGIOSKOP takes the compromise



Siemens...
an investment in diagnostic confidence.

out of angiography.

When you invest in angiography equipment, there's no need for compromise. You can select an imaging system designed to optimize operator efficiency and clinical versatility. The ANGIOSKOP overcomes the typical limitations of other systems. That's why it's the "no-compromise" system. See for yourself. Compare the facts and discover the ANGIOSKOP advantage.

A.P./P.A. Studies

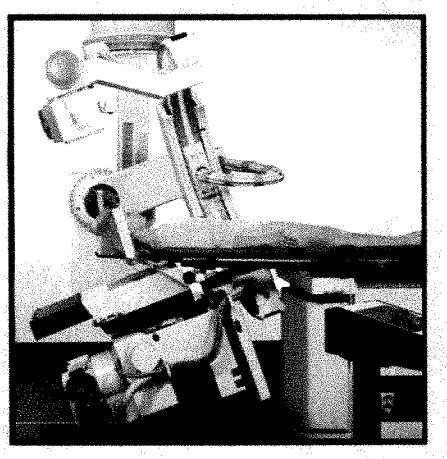
The typical compromise: True a.p. projection is not possible.
The ANGIOSKOP advantage: A C-arm system that easily positions to a.p. for classic peripheral studies including leg arteriography.

Oblique Studies

The typical compromise: Restricted patient access.
The ANGIOSKOP advantage: An imaging system that doesn't get in the way between clinician and patient. Our C-arm design eliminates the usual hinderances and provides easy access.

Contact Studies

The typical compromise: Inadequate working height.
The ANGIOSKOP advantage: Vertical adjustment of the isocenter to maintain an efficient and comfortable working height at all times.



Cine Studies

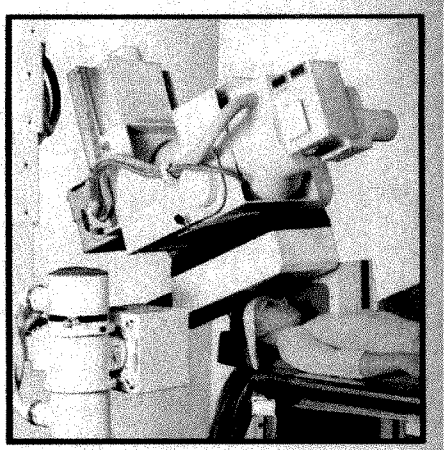
The typical compromise: Limited imaging applications.
The ANGIOSKOP advantage: A universal system that is well suited for cine technique and adaptable to perform all imaging modalities.

Focal Spot Selection

The typical compromise: Double focus tubes.
The ANGIOSKOP advantage: A unique triple focus tube for full range performance, minimizing geometric or motion unsharpness.

X-Ray Generator System

The typical compromise: Complex technique selection.
The ANGIOSKOP advantage: A new special procedure D.C. generator—the PANDOROS 1200A. Features convenient anatomic program selection from a single control desk for all modalities.



...And Digital Subtraction Angiography

The ANGIOSKOP allows all projection capabilities essential for optimum digital subtraction angiography. And Siemens offers a choice of digital imaging systems to match your clinical requirement.

To learn more about how the ANGIOSKOP can help uncomplicate your angiographic procedures, contact your local representative or

THE ALPHA UNIVERSE

...is the Catapres® universe of central alpha control* for all kinds of hypertensives

No contraindications to Catapres — you can prescribe it for:**

- **Asthmatic hypertensives**
  Does not act directly on beta$_2$ receptors of the lungs (blocking these receptors induces bronchospasm).
- **Diabetic hypertensives**
  Lowers blood pressure without impairing oral antidiabetic effectiveness.
- **Hypertensives with renal insufficiency**
  Lowers blood pressure without long-term reduction of cardiac output. (Does not reduce renal perfusion or GFR.)
- **Hypertensives with congestive heart failure**
  Does not depress myocardial contractility.
- **Stress-induced hypertension**
  Inhibits sympathetic nervous activity centrally and does not elevate plasma catecholamines.
- **Elderly hypertensives**
  Recommended in isolated systolic hypertension in the elderly.[1]

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

**Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

1. Statement on Hypertension in the Elderly, Revised April, 1980. Approved by the National High Blood Pressure Education Program Coordinating Committee.

Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

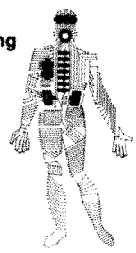
Hypertension

Please see brief summary of PI for warnings, precautions, and adverse reactions.

THE ALPHA UNIVERSE

Tablets of 0.1, 0.2, 0.3 mg

Catapres®
(clonidine HCl)
Hypertension



Catapres®

(clonidine hydrochloride)

Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

Under license from Boehringer Ingelheim International GmbH

The Alpha Universe, a painting by Arthur Lidov, commissioned by Boehringer Ingelheim Ltd.

Lidov's work, the second in a series on central alpha action, interprets the Alpha Universe on many levels...the universe of patients who can benefit from the central alpha control of Catapres...the special world of patient/clinician interaction... the internal universe within each patient that determines or modifies his therapy...and the universe of medicine itself. Lidov is a painter whose art invites us to share his own fascination with the creativity inherent in science.

If you like this painting, we would be pleased to send you a handsome reproduction suitable for framing...with our compliments.

Norpace
(disopyramide phosphate) 100-mg and 150-mg capsules

Norpace CR controlled release
(disopyramide phosphate) 100-mg and 150-mg capsules

Before prescribing Norpace (disopyramide phosphate) or Norpace CR, please consult current complete prescribing information, a summary of which follows: **Indications**: For suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications**: Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace or Norpace CR therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of Norpace or Norpace CR, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. Precautions**: Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions**: Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration**: Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses. The recommended dosage schedule for most adults is either 150 mg every six hours for immediate-release Norpace or 300 mg every 12 hours for Norpace CR. For patients less than 110 pounds (50 kg) the recommended dosage is either 100 mg every six hours for immediate-release Norpace or 200 mg every 12 hours for Norpace CR. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg of immediate-release Norpace every six hours, with subsequent dosage adjustments made gradually with close monitoring. **See current complete prescribing information for dosage recommendations, including pediatric use.**

New Norpace® CR controlled release

(disopyramide phosphate)

100-mg and 150-mg capsules

Simple dosage schedule *Just two capsules b.i.d. reduce the potential for skipped doses*

Enhanced compliance *Norpace CR helps to establish continuous effective dysrhythmia therapy... especially well suited to long-term use.*

Effective dysrhythmia therapy *Bioavailability studies demonstrate that Norpace CR q12h provides therapeutic blood levels equivalent to immediate-release Norpace (disopyramide phosphate) q6h, with less variability.*

The most commonly seen side effects from disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties. Please see the brief summary of prescribing information on the preceding page.

SYMPOSIUM ON VERAPAMIL THERAPY FOR ANGINA PECTORIS
PART III: STUDIES IN EFFORT-RELATED ANGINA

MILTON PACKER, MD, Guest Editor, and WILLIAM H. FRISHMAN, MD, Guest Co-Editor

Verapamil Therapy for Stable Exertional Angina Pectoris

DONALD A. WEINER, MD, and MICHAEL D. KLEIN, MD

Clinical and exercise responses to therapy with the calcium-channel blocking agent verapamil were assessed in 26 patients with stable exertional angina pectoris using a double-blind, placebo-controlled, randomized crossover study design. Verapamil, 480 mg daily, reduced the frequency of angina attacks (5.6 ± 7.3 to 2.2 ± 3.0 attacks per week, $p < 0.001$) and number of nitroglycerin tablets consumed (3.4 ± 4.9 to 1.2 ± 2.5 tablets per week, $p < 0.05$), and increased exercise duration (6.4 ± 2.1 to 7.5 to 1.8 minutes, $p < 0.001$) (all data are mean ± standard deviation). These changes were significantly better than those seen with placebo. These beneficial effects of verapamil were related to significant reduction in the heart rate-systolic blood pressure product during submaximal exercise. Adverse effects from verapamil were few and consisted primarily of constipation in 6 patients. A total of 193 patients had been entered in 6 independent clinical trials, which have compared verapamil with placebo for the treatment of stable exertional angina pectoris, using a similar study design. The combined evidence from all these studies indicates that verapamil is a highly effective and safe drug for the treatment of stable effort-related angina pectoris.

Conventional drug therapy for the treatment of exertional angina pectoris has relied on the use of nitrate preparations[1,2] and beta-adrenergic blocking agents.[3,4] These medications reduce the major determinants of myocardial oxygen demand at rest and during any level of exercise.[5,6] In some patients, however, troublesome side effects can occur.[7] Other patients fail to achieve satisfactory remission of symptoms, even with combinations of these drugs.

A new class of antianginal drugs which inhibit the influx of calcium ions across myocardial and vascular smooth muscle and reduce automaticity in sinoatrial cardiac pacemaker cells[8] has been developed. These pharmacologic actions serve to reduce heart rate and systolic blood pressure, which might benefit patients with exercise-induced angina pectoris.[9-11]

This study reports the subjective and objective improvement in 26 patients with stable angina of effort treated with the calcium entry blocker drug verapamil. The results of this trial, published previously,[12] are reviewed together with the results of 6 other studies, all of which utilized a double-blind, placebo-controlled, crossover study design.

Methods

Patient population: Twenty-six men with a mean age of 55 years (range 30 to 72) were enrolled in the protocol during a 17 month period. The selection criteria included a minimum of 5 episodes of angina pectoris per week in a stable pattern and an abnormal control treadmill test with both ischemic (1 mm or greater) S-T segment depression and angina during exercise testing. All patients had either a radionuclide or angiographic left ventricular ejection fraction greater than 40%.

Study design: The precise details of the protocol have been reported elsewhere.[12] In brief, it consisted of the following phases: an initial 2 week, placebo stabilization phase; a single-blind phase in which 2 doses of verapamil, 320 and 480 mg per day in 4 divided doses, were tested sequentially for 1 week

periods; and a double-blind, randomized phase in which the patients received either placebo or verapamil, 480 mg per day, for 2 week periods, followed by a 1 week drug tapering period. A 1 week buffer period separated the two randomized phases.

Data collection: Subjective evaluation consisted of analyzing a diary in which the patients recorded the number of anginal attacks and nitroglycerin tablets consumed. Objective evaluation included data recorded during performance of 8 treadmill exercise tests using the Bruce protocol[13] during the 12 week protocol. The heart rates and blood pressures were recorded at rest, during submaximal exercise (defined as the end of stage 1 of exercise), and at maximal exercise. The peak S-T segment depression, the time from the start of exercise to the onset of 1 mm of S-T segment depression, and the total duration of exercise were also analyzed.

Statistics: One-way analysis of variance was used to determine whether there was significant difference in the group mean values. If the analysis of variance indicated a significant difference in the mean values for a parameter, a two-tailed Student's t test was applied. Probabilities were considered significant at the 0.05 level. All values are expressed as means ± standard deviation.

Results

Single-blind phase: In the single-blind phase, the 26 patients reported subjective improvement during therapy with verapamil. The mean frequency of anginal attacks decreased from 11.7 ± 8.7 attacks per week on placebo to 3.7 ± 6.0 attacks per week on verapamil, 320 mg daily, and to 3.7 ± 5.8 attacks per week on verapamil, 480 mg daily (placebo versus both dose levels of verapamil, $p < 0.05$) (Fig. 1). Nitroglycerin consumption was also significantly reduced during therapy with both doses of verapamil compared with placebo: from 4.5 ± 5.7 tablets per week with placebo to 1.9 ± 3.1 tablets per week with verapamil, 320 mg, and 2.1 ± 4.0 tablets per week with verapamil, 480 mg ($p < 0.05$). The differences observed between the lower and higher doses of verapamil were not significant. Objective improvement was also documented by a significant ($p < 0.001$) increase in exercise duration during therapy with verapamil, 320 mg per day (6.9 ± 2.3 minutes) and 480 mg per day (8.0 ± 1.7 minutes) as compared with placebo (5.1 ± 1.6 minutes). The exercise duration with the higher dose of verapamil was significantly greater than that seen with the lower dose (Fig. 2). The peak S-T segment depression during exercise was significantly reduced with verapamil compared with placebo only at the higher dose of verapamil (Fig. 3).

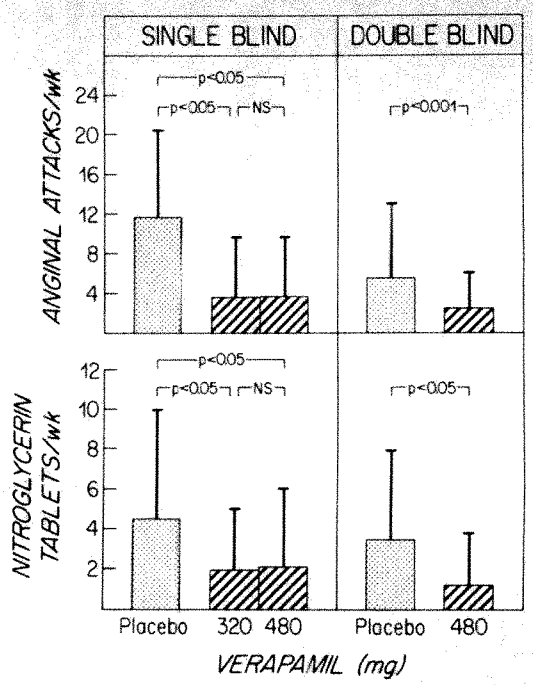

FIGURE 1. Effect of verapamil therapy compared with placebo in the number of anginal attacks and nitroglycerin tablets ingested per week in the single-blind and double-blind phases. Values are expressed as mean ± standard deviation.

Double-blind phase: Since, during the single-blind phase, no patient had major adverse effects with the higher dose of verapamil and many showed increased exercise tolerance with higher compared with lower doses of the drug, every patient was treated with either 480 mg of verapamil or identical placebo capsules during

TABLE I Previous Double-Blind Placebo-Controlled Studies Evaluating the Efficacy of Verapamil

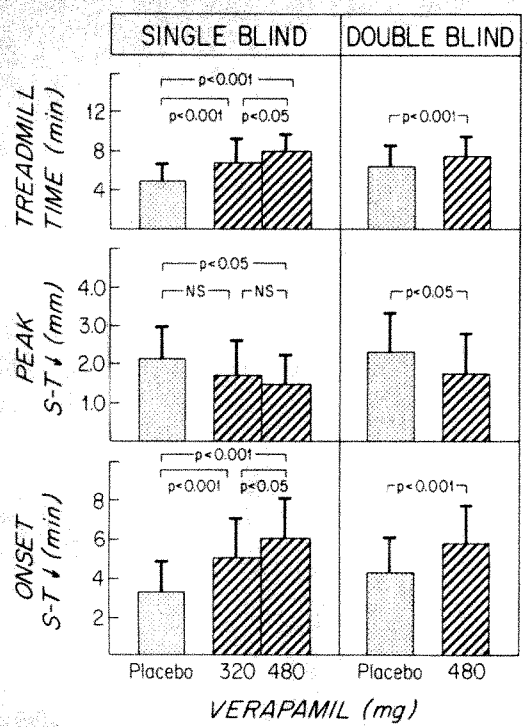

FIGURE 2. Effect of verapamil therapy compared with placebo on treadmill time, peak S-T segment depression, and time to onset of S-T segment depression in the single-blind and double-blind phases. Values are expressed as mean ± standard deviation.

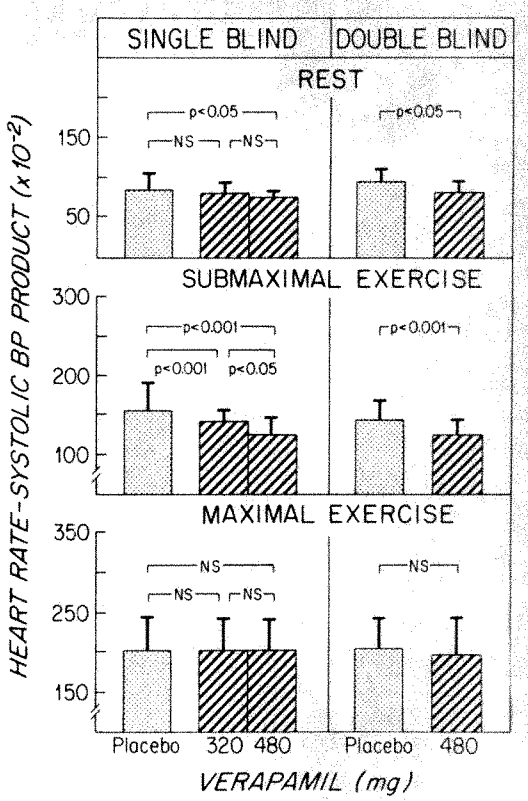

FIGURE 3. Effect of verapamil therapy compared with placebo on the product of the heart rate and systolic blood pressure at rest, and submaximal and maximal exercise in the single-blind and double-blind phases. Values are expressed as mean ± standard deviation.

the randomized double-blind crossover phase. During the double-blind phase, patients obtained benefits from verapamil that were similar to those seen during the single-blind trial. Verapamil reduced mean anginal frequency (from 5.6 ± 7.3 to 2.2 ± 3.0 attacks per week, $p < 0.001$) nitroglycerin consumption (from 3.4 ± 4.9 to 1.2 ± 3.0 tablets per week, $p < 0.05$, Fig. 1), and the rate-pressure product at rest and during submaximal exercise (Fig. 2). Verapamil increased the time to onset of 1 mm S-T segment depression (Fig. 2) and increased exercise duration (from 6.4 ± 2.1 to 7.5 ± 1.8 minutes, $p < 0.001$, Fig. 3). Not all patients responded to verapamil therapy with a marked increase in exercise duration, however. Ten patients had only a modest (less than 10%) increase in exercise duration while receiving verapamil instead of placebo, whereas 2 other patients had a slight reduction in exercise time with verapamil.

Control and placebo tests: There were no significant differences between the baseline control test (before the start of the protocol) and the placebo test performed at the end of the 2 week, single-blind phase. Comparison of the placebo tests before the single-blind and double-blind phases, performed approximately 7 to 10 weeks apart, did show a significant increase in exercise duration and a reduction in the rate-pressure product during submaximal exercise during the second test.

Adverse effects: No patient had to be withdrawn from the study because of significant adverse effects. One patient had abnormal liver function at the end of the double-blind phase and was withdrawn from a long-term follow-up study. In 6 of the patients (22%) constipation developed approximately 1 week after starting verapamil, but only 3 of them required treatment with stool softeners. Five patients had a prolongation of the P-R interval by 20 to 40 ms with verapamil, but did not exhibit first-degree heart block. One patient with preexisting first-degree block had no further lengthening of the P-R interval while receiving verapamil. One patient manifested a junctional rhythm, which subsided during treadmill exercise, while taking verapamil.

Discussion

Present study: The results of this study document both subjective and objective improvement in patients with stable angina of effort receiving verapamil, 480 mg per day. Mean anginal attack frequency was decreased 61% and nitroglycerin consumption was reduced 65% compared with the placebo responses during the double-blind phase; the duration of time on a treadmill increased 17%. Verapamil produced few adverse effects; these consisted primarily of constipation, which was remedied by stool softeners or dietary adjustment.

Previous studies (Table I): Six other double-blind, randomized, crossover, placebo-controlled clinical trials have evaluated verapamil therapy in patients with

stable angina of effort. Trials not using such a study design are not considered in this report.

Neumann et al.[14] evaluated verapamil, 120 mg daily for 6 weeks, in 30 nursing home patients (15 men and 15 women) averaging more than 75 years of age. Verapamil significantly decreased the number of nitroglycerin tablets consumed, as compared with a 6 week placebo period.

Phear[15] compared verapamil, 240 mg daily, with placebo in 20 patients (13 men and 17 women, mean age 58 years) with each agent given for 2 weeks. No reduction in the frequency of anginal attacks or nitroglycerin consumption was noted. No buffer period was present between randomization phases, however, and the possibility of lingering verapamil action in some patients subsequently randomized to placebo was not considered.

Andreasen et al.[16] assessed subjective and objective variables in a multicenter Danish study involving 47 patients (38 men and 19 women, aged 48 to 71 years) which compared verapamil, 240 mg daily, with placebo, each given for 4 weeks. Verapamil significantly reduced the frequency of anginal attacks and nitroglycerin tablets consumed. Exercise capacity, assessed from the amount of time required to produce ischemic S-T depression during bicycle ergometry, was significantly enhanced. Adverse effects from verapamil were minimal; only 3 patients reported constipation.

More recent studies have validated the subjective and objective benefits of verapamil in the treatment of effort-induced angina. Bala Subramanian et al.[11] administered verapamil, 360 mg daily, or placebo to 28 patients, 25 men and 3 women, for 2 weeks each, and then treated each patient with open-label verapamil for 4 weeks. Compared with placebo, verapamil significantly increased mean treadmill tolerance by 38% during the double-blind phase, and then by an *additional* 21% during open-label therapy. Verapamil therapy resulted in a significant reduction in anginal attacks (47%) and nitroglycerin consumption (45%) during the double-blind phase of the study. Seven patients had constipation requiring laxative therapy. Two patients had mild first-degree heart block.

Pine et al.[17] compared verapamil with placebo in 30 patients with effort-related angina pectoris who underwent a more detailed evaluation of response. Each patient received verapamil, 240, 360, and 480 mg per day, for 1 week in a single-blind fashion; this was followed by a double-blind placebo-controlled randomized phase in which placebo was compared with verapamil, administered in the dose which produced the greatest improvement in exercise tolerance during the single-blind phase. During the double-blind phase, verapamil significantly reduced the mean anginal attack frequency 47% and nitroglycerin consumption 55%, and significantly increased exercise capacity on the treadmill 42%. Seven patients had adverse reactions (rhythm disturbances in 3 patients, pulmonary edema in 1, and noncardiac symptoms in 3) with 480 mg daily of verapamil, all of which disappeared with a reduction in the dose to 360 mg daily. In these 7 patients the improvement in exercise duration on the lower dose of the drug (360 mg daily) was similar to that observed with the higher dose (480 mg daily).

Tan et al.,[18] in their evaluation of 12 men aged 45 to 73 years, found that verapamil, 320 mg daily for 4 weeks, produced a 78% reduction in anginal attacks and a 20% improvement in exercise duration on a treadmill, when compared with placebo therapy for 4 weeks. The ejection fraction declined from 40 ± 9% (at rest) to 35 ± 11% (at peak effort) during placebo therapy, whereas during verapamil therapy the ejection fraction did not decrease during exercise (44 ± 8% at rest and 45 ± 12% at peak effort).

These 6 studies,[11,14–18] combined with ours,[12] comprise 193 patients treated with verapamil in double-blind, placebo-controlled, randomized protocols; all but 1 study[15] showed significant improvement during treatment with verapamil. The dose of verapamil ranged from 120 to 480 mg daily; adverse effects were infrequent and minor in all but 1 study,[17] in which more frequent adverse reactions were observed when a dose of 480 mg daily was employed. Since 82% of the patients studied were men, it is unclear whether verapamil has similar antianginal effects in women.

In evaluating the efficacy of new antianginal medications, careful attention must be given to the recruitment of patients with stable mechanical and electrical heart function who will be reliable in taking both active drug and placebo pills. Subjective (anginal attack frequency and nitroglycerin consumption) and objective (treadmill performance) measures of drug effect should be evaluated concurrently. Patients selected should have reproducible exercise-induced angina, preferably within 3 to 6 minutes,[19] on a standard exercise protocol in order to avoid distress from leg fatigue or hyperventilation at higher intensities of exercise. In analyzing group patient exercise data, consideration should be given to placebo effects, to training effects during sequential exercise tests,[20,21] and to interpatient variability during control or placebo exercise tests.

In the present protocol, comparison of single and subsequent double-blind placebo tests revealed that the treadmill time increased and the submaximal exercise heart rate and rate-systolic blood pressure product decreased significantly after the patients had completed a minimum of 5 treadmill tests. These changes might have been due to a training effect, since blood verapamil and norverapamil levels measured at the time of the double-blind placebo test were 0 to 18 ng/ml in 24 patients. Such minute amounts of blood verapamil would have been unlikely to reflect lingering drug action on the heart. A further significant increase in treadmill performance induced by verapamil, as compared with placebo, occurred during the double-blind phase of the study. Since training effects, if present, would probably have been completed before the initiation of the double-blind study phase, these results confirmed the exercise-enhancing capacity of verapamil.

In most studies on new antianginal therapy, some patients will respond better than others. Comparison of individual responses may elucidate mechanisms involved in a greater therapeutic response. In our study, 12 patients showed minimal (less than 10%) or no im-

provement in exercise duration while receiving verapamil, compared with placebo, in the double-blind study phase. These 12 patients did not differ from the other 14 patients with respect to baseline anginal frequency or nitroglycerin consumption. However, the mean exercise duration on the initial baseline exercise test before entry into the study was 23% less ($p < 0.05$) in the 14 patients with a therapeutic response to verapamil during the double-blind phase than in patients with minimal responses. These findings indicate that verapamil may confer its greatest benefit on patients whose exercise capacity is most restricted by angina before entry into the study.

Mechanism of verapamil action: In the present study verapamil, compared with placebo, significantly decreased both the resting and submaximal heart rate, the submaximal systolic blood pressure, and the resting and submaximal rate-pressure product during the double-blind phase. We observed a greater effect on heart rate than on systolic blood pressure; other investigators have noted just the opposite.[22] Regardless of which effect predominates, these responses can be explained by the negative chronotropic actions of verapamil,[23,24] as well as its dilating effects on systemic arterioles.[25,26] These findings are consistent with the hypotensive actions of verapamil during rest and bicycle ergometry in patients with essential hypertension.[27]

Clinical implications and perspectives: Thus, verapamil is a safe, effective drug in the treatment of patients with stable exertional angina pectoris. The effective dose ranges from 240 to 480 mg daily in 3 or 4 divided doses. Adverse effects are infrequent and mild, and consist primarily of constipation and prolongation of atrioventricular conduction. Overt congestive heart failure may occur rarely in patients with preserved left ventricular function. Abnormal hepatic function has been reported infrequently after verapamil therapy. In the treatment of angina of effort, verapamil may offer special advantages to patients who also have bronchial asthma or peripheral vascular disease. Such patients are likely to have an exacerbation of these disorders during therapy with beta-adrenergic blocking agents, when these are used in doses required to alleviate exercise-induced angina.[6,7]

Calcium Channel Blockade as Primary Therapy for Stable Angina Pectoris

A Double-Blind Placebo-Controlled Comparison of Verapamil and Propranolol

V. BALA SUBRAMANIAN, MD, MICHAEL J. BOWLES, MRCP, ANTHONY B. DAVIES, MRCP, and EDWARD B. RAFTERY, MD

The effectiveness and safety of the beta-adrenergic blocking agent propranolol and the calcium channel antagonist verapamil were compared in 22 patients with chronic stable angina pectoris using a double-blind randomized placebo-controlled crossover protocol. The double-blind phase was preceded by a 2 week single-blind placebo period, followed by randomization to either either 4 weeks' therapy with verapamil, 360 mg/day, or propranolol, 240 mg/day, followed by crossover to the other drug. Both verapamil and propranolol increased exercise tolerance (5.5 ± 0.4 minutes with placebo, 7.8 ± 0.5 minutes with propranolol [$p < 0.001$], and 9.1 ± 0.5 minutes with verapamil [$p < 0.001$]), but the increase with verapamil was significantly greater ($p < 0.01$). Both drugs prolonged the exercise duration to 1 mm S-T depression (3.3 ± 0.4 minutes with placebo, 5.7 ± 0.5 minutes with propranolol [$p < 0.001$] and 5.5 ± 0.6 minutes with verapamil [$p < 0.001$]); the degree of improvement was similar with both active drugs. Both drugs decreased the resting heart rate (76 ± 3 beats/min with placebo, 56 ± 2 beats/min with propranolol [$p < 0.001$], and 71 ± 3 beats/min with verapamil [$p < 0.01$]), but the heart rate decreased more with propranolol than with verapamil ($p < 0.001$). Neither drug produced significant adverse reactions. This study, along with 8 similar double-blind placebo-controlled randomized investigations which have compared verapamil with propranolol, indicate that verapamil is as effective and safe as propranolol in relieving symptoms and improving exercise tolerance in patients with chronic stable angina pectoris and may be considered a first-line therapeutic agent in patients with ischemic heart disease.

Beta-adrenergic blocking drugs are presently the primary therapeutic modality in the management of patients with angina pectoris.[1–6] Although many patients have significant improvement in symptoms after the institution of beta-blocker treatment, these drugs can cause depression and fatigue, prevent recognition of hypoglycemic episodes in insulin-dependent diabetics, and produce clinical deterioration in patients with peripheral vascular disorders and obstructive pulmonary disease.[7] Alternative first-line antianginal therapy is needed for the management of effort-related ischemia in such patients, as well as those who remain symptomatic despite adequate therapy with nitrates and beta-blocking agents.

The development of drugs that block calcium influx into cardiac muscle and vascular smooth muscle has led to the application of such agents in the treatment of angina pectoris.[8–11] Of the available agents, verapamil has been in clinical use almost as long as the beta blockers, and it possesses powerful antianginal properties that provide sustained long-term benefit.[12–15] Verapamil has been shown highly effective in the

management of patients with angina at rest,[16–18] and it is superior to propranolol in this clinical condition.[19] Verapamil is also highly effective in effort-related angina,[13,20,21] and a number of clinical trials have shown that it is comparable or superior to propranolol in patients with exertional symptoms.[22–30]

The present report details the results of a double-blind placebo-controlled randomized crossover trial comparing verapamil and propranolol in patients with stable effort-related angina pectoris; a preliminary report of these results was published in 1981.[30] Our data are similar to those of 8 other studies[22–29] which have employed a similar double-blind crossover study design; these are also reviewed herein. Together, these data indicate that verapamil is a safe and effective alternative to propranolol in patients with chronic stable angina pectoris and may be a first-line drug for many patients with ischemic heart disease.

Methods

Twenty-five patients with effort-related stable angina pectoris (age range 41 to 69 years, 22 men and 3 women) entered the trial. All patients had chest pain (at least 4 attacks per week) relieved by rest and by sublingual nitroglycerin and at least 1 mm horizontal S-T depression on standardized treadmill exercise testing. Coronary artery disease was confirmed either by coronary arteriography or by the occurrence of a transmural myocardial infarction infarction within the last 12 months.

Patients with a recent myocardial infarction (within the last 4 months), with unstable or accelerating symptoms, with clinical congestive heart failure or resting blood pressure over 160/100 mm Hg, or with insulin-dependent diabetes mellitus were excluded from the trial. No patient received digitalis, diuretics or other cardiovascular agents before or during the study. Any patient showing more than 0.5 mm S-T depression on standing, with hyperventilation or with Valsalva maneuvers, or who failed to develop classic angina on the initial diagnostic treadmill exercise test with at least 1 mm S-T segment depression in both bipolar leads, was not entered into this trial.

Trial design: After an initial 2 week placebo run-in period, all 25 patients were randomized to propranolol, 240 mg daily, or verapamil, 360 mg daily, administered in 3 divided doses for 4 weeks, followed by crossover to the alternate drug. Because 4 weeks elapsed between each exercise test, no washout period was incorporated. All evaluations were repeated at the end of placebo and at 4 and 8 weeks of active drug therapy.

All patients were examined for development of cardiac failure, and side effects were noted in a standard questionnaire. All patients gave informed consent for participation in the trial and the project was approved by the Hospital Ethical Committee.

Exercise testing: All tests were performed using a motor-driven treadmill; the speed and gradient were regularly calibrated and the program (Table I) was governed by a computer (Marquette Computer Assisted System for Exercise). Two bipolar leads (CM5 and CC5) were continuously recorded before, during, and after exercise in a 25:1 compressed format. Digital printouts of S-T depression at the J point, S-T slope, heart rate, and ectopic count were generated for every minute of the test and for a final analog trend plot of each complete test.[31] Systolic blood pressure was measured every 3 minutes and at termination of exercise with a mercury sphygmomanometer.

TABLE I Treadmill Protocol

Stage	Time (min)	Speed (miles/h)	Gradient (% Incline)
1	3	2	0
2	3	4	4
3	3	3	8
4	3	3	12
5	3	3	16
6	3	3	20
7	3	4.5	20

All exercise tests were limited by angina, dyspnea, fatigue, or pain in the legs. All were performed in the morning 90 to 150 minutes after the last dose of drug and after 30 minutes' rest in a temperature-controlled laboratory. The standard safety precautions as recommended by the American Heart Association were followed.[32]

From the computer printouts, we derived the exercise time (time taken to develop angina or fatigue), resting heart rate, maximal heart rate, double product (systolic blood pressure × heart rate/100), and peak S-T depression in CM5. The following variables were calculated from the computer printouts[30,31]: (1) workload = the product of the distance walked in kilometers and the sine angle of the treadmill in degrees, (2) 1 mm time and 2 mm time = time required to produce 1 and 2 mm S-T segment depression in both bipolar leads CM5 and CC5, (3) S-T segment depression at the same workload = the magnitude of S-T segment depression at the maximal workload achieved in each patient during placebo therapy.

Ambulatory monitoring: Continuous ambulatory monitoring of 2 channels of the electrocardiogram (CM5 and CC5) was performed using a frequency-modulated tape recorder with a quartz controlled time channel (Oxford Medilog Mark II) for a minimum of 24 hours.[33] All tapes were visually analyzed for prolongation of the P-R interval or higher degrees of heart block. Mean hourly heart rates were obtained using a computer program. The tapes were then played into a minicomputer which stored minute-averaged values of mean, minimal, and maximal heart rate and S-T segment values for 24 hours in a 5.25 inch floppy disc. Software analysis enabled acquisition of a number of objective variables such as maximal S-T depression, episodes of S-T depression of 1 mm in 24 hours, and the number of minutes in which the heart rate exceeded a preset figure (100 beats/min).

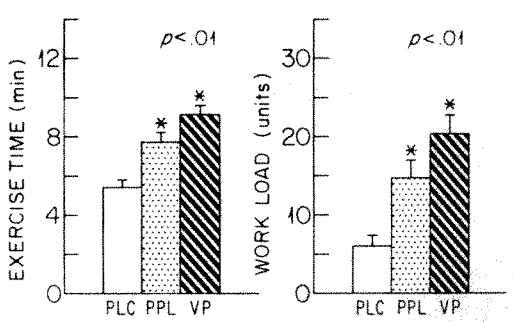

FIGURE 1. Duration of exercise (**left panel**) and workload (**right panel**) during therapy with placebo (PLC), propranolol (PPL), and verapamil (VP). Data are shown as means ± standard error of the mean. **Asterisks** indicate significance of differences between active drug therapy compared with placebo. P values indicate significance of differences between propranolol and verapamil.

TABLE II Comparative Effects of Placebo, Propranolol, and Verapamil in Patients With Chronic Stable Exertional Angina*

	Placebo	Propranolol (240 mg/day)	Verapamil (360 mg/day)	A	B	C
Exercise time (min)	5.5 ± 0.4	7.8 ± 0.5	9.1 ± 0.5	<0.001	<0.001	<0.01
Workload (units)	6.1 ± 1.4	14.8 ± 2.2	20.4 ± 2.4	<0.001	<0.001	<0.01
Resting heart rate (beats/min)	76 ± 3	56 ± 2	71 ± 3	<0.001	<0.01	<0.001
Maximal heart rate (beats/min)	135 ± 3	104 ± 3	130 ± 3	<0.001	NS	<0.001
Double product at peak effort (beats × mm Hg/min)	216 ± 8	164 ± 7	204 ± 6	<0.001	NS	<0.001
1 mm time (min)	3.3 ± 0.4	5.7 ± 0.5	5.5 ± 0.6	<0.001	<0.001	NS
2 mm time (min)	4.3 ± 0.5	7.3 ± 0.7	7.1 ± 0.9	<0.001	<0.001	NS
S-T↓ at peak effort (mm)	2.4 ± 0.2	1.7 ± 0.1	2.2 ± 0.2	<0.01	NS	NS
S-T↓ at same workload as placebo (mm)	2.3 ± 0.2	1.0 ± 0.1	1.3 ± 0.2	<0.001	<0.001	NS
Heart rate at same workload as placebo (beats/min)	131 ± 3	94 ± 3	116 ± 3	<0.001	<0.001	<0.001

* Data are expressed as mean ± standard error of the mean. The 3 columns on the right indicate p values for level of significance of differences between the 3 treatment periods, where A compares placebo with propranolol, B compares placebo with verapamil, and C compares propranolol with verapamil. NS = not significant; S-T↓ = S-T segment depression.

Statistical analysis: Group data are presented as means ± standard error of the mean. Statistical analyses were performed by the *t* test for paired data.

Results

Twenty-two patients (20 men and 2 women) with an age range of 41 to 69 years completed the trial.

Exercise duration (Fig. 1, Table II): The duration of exercise was prolonged by both propranolol ($p < 0.001$) and verapamil ($p < 0.001$), but the improvement seen with verapamil was significantly greater ($p < 0.01$). All 22 patients stopped exercise on the treadmill because of angina during the placebo phase, and 18 stopped the treadmill test because of angina during treatment with propranolol, but only 12 patients had angina during exercise testing with verapamil therapy. The exercise time with verapamil was longer than with propranolol in 17 patients, shorter in 4 patients, and similar in 1 patient. The maximal workload achieved averaged 6.1 ± 1.4 units with placebo, 14.8 ± 2.2 units with propranolol ($p < 0.001$ versus placebo), and 20.4 ± 2.4 units with verapamil ($p < 0.001$ versus placebo and $p < 0.01$ versus propranolol).

Exercise variables and S-T segment responses (Fig. 2, Table II): The time to 1 and 2 mm S-T segment depression during placebo therapy was prolonged similarly by both verapamil and propranolol. At the same workload achieved during placebo therapy, propranolol reduced the magnitude of S-T depression (from 2.3 ± 0.2 mm to 1.0 ± 0.1 mm, $p < 0.001$), which was similar to the reduction seen with verapamil (1.3 ± 0.2 mm, $p < 0.001$). However, the magnitude of S-T depression at maximal exercise was reduced only by propranolol ($p < 0.01$) and not by verapamil; this degree of S-T depression, however, was seen after 9.1 minutes of exercise during verapamil therapy, compared with only 5.5 minutes on placebo. The difference in the effect of the 2 drugs on S-T segment depression at maximal exercise was related to our observation that only propranolol therapy was associated with a significant reduction in double-product at peak effort ($p < 0.001$); this effect was not seen with verapamil.

Compared with placebo (76 ± 3 beats/min), both drugs reduced the resting heart rate (to 56 ± 3 beats/min with propranolol and to 71 ± 3 beats/min with verapamil); however, the effects of propranolol on heart rate were more pronounced ($p < 0.01$). The heart rate at the same workload achieved at peak effort during placebo therapy was reduced by both drugs; again, the effects of propranolol were more pronounced. Propranolol decreased the heart rate during maximal exercise ($p < 0.001$), but verapamil did not.

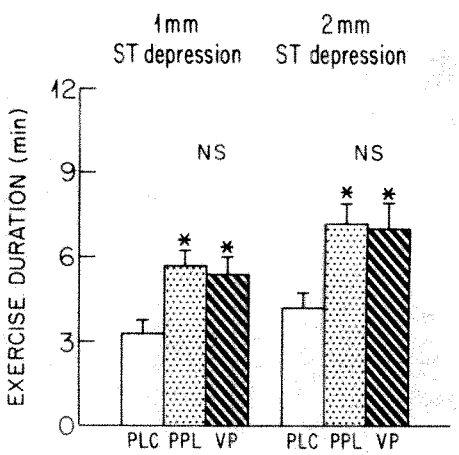

FIGURE 2. Time on a treadmill exercise test to the development of 1 and 2 mm S-T depression during treatment with placebo (PLC), propranolol (PPL), and verapamil (VP). Data are shown as means ± standard error of the mean. **Asterisks** indicate significance of differences between active drug therapy compared with placebo. NS indicates that the differences between propranolol and verapamil therapies were not significant.

TABLE III Double-Blind Placebo-Controlled Randomized Clinical Trials Comparing Verapamil and Propranolol*

Reference	Country & Year	Patients (n)	Duration	Methods	V Daily Dose (mg)	Beta-Blocking Agent & Dose (mg)	Findings
Sandler et al.[22]	UK (1968)	16	4 weeks	1,2	120,360	Propranolol, 300	Both drugs equal at higher dose of V
Liveseley et al.[23]	UK (1973)	32	4 weeks	1,2	240,360	Propranolol, 300	Both drugs equal at higher dose of V
Fagher et al.[24]	Sweden (1977)	13	4 weeks	1,2	240	Practolol, 300	V effective, P was not; trial-abbreviated
Johnson et al.[25]	US (1981)	18	2 weeks	1,2,3,4	320,480	Propranolol, 160 & 320	Both drugs equal at higher doses of V & P
Sadick et al.[26]	Australia (1981)	18	3 weeks	1,2,4	320	Propranolol, 320	Both drugs equal
Leon et al.[27]	US (1981)	11	48 hours	1,2	480	Propranolol, range 160–320	V superior
Frishman et al.[28]	US (1981)	20	4 weeks	1,2	480	Propranolol, 320	V superior
Arnman and Ryden[29]	Sweden (1982)	24	4 weeks	1,2	360	Metoprolol, 200	V superior
Bala Subramanian et al. (present study)	UK (1982)	22	4 weeks	1,2,3	360	Propranolol, 240	V superior

* Duration refers to number of weeks treated with each drug. Methods: 1 = clinical evaluation; 2 = exercise testing; 3 = Holter monitoring; 4 = radionuclide studies. P = propranolol or practolol; UK = United Kingdom; US = United States; V = verapamil; Year = year of publication.

Twenty-four ambulatory monitoring (Fig. 3): The pooled mean hourly heart rate with placebo, verapamil, and propranolol was related to clock time and expressed as a continuous curve (Fig. 3). Both drugs reduced the heart rate throughout the day, but the reduction with propranolol was greater. The total area of S-T depression was calculated for the entire 24 hours and divided by the number of minutes in which S-T depression occurred to yield an average S-T level. The mean S-T depression during placebo (-1.5 ± 0.2 mm) was reduced similarly by propranolol (-0.7 ± 0.2, $p < 0.001$) and by verapamil (-0.9 ± 0.2, $p < 0.001$).

Adverse reactions: Both drugs were well tolerated with few side effects. Constipation was a constant feature with verapamil and tiredness or lethargy with propranolol. Two patients were withdrawn during the propranolol phase because of dyspnea at rest and severe hypotension. One patient had a myocardial infarction and died during the verapamil phase. Autopsy revealed severe triple-vessel disease with total obstruction of the left anterior descending artery. No P-R interval prolongation on the electrocardiogram was observed in any patient during either active drug phase.

Discussion

Results of the present trial: Since beta-adrenergic blocking agents are presently the therapeutic agents of choice in prevention of effort-induced ischemic chest pain,[1–6] any new antianginal agent should be compared with the beta-blocking drugs in order to establish its relative efficacy and safety. The present report indicates that both verapamil and propranolol prolong the duration of exercise before the appearance of ischemic S-T segment depression and anginal pain. Although all patients were limited by chest pain during placebo therapy, 4 patients during propranolol therapy and 10 patients during verapamil therapy failed to develop angina and stopped exercise because of dyspnea or leg fatigue. Propranolol appeared to exert its effects by a reduction in resting heart rate and in the rate-pressure product at peak effort; hence, the drug reduced the major determinants of myocardial oxygen consumption and, accordingly, reduced the maximal S-T segment depression achieved with exertion. Verapamil produced moderate reductions in heart rate at rest and at submaximal workloads, but it did not decrease the rate-pressure product or the magnitude of S-T segment depression at peak effort. Thus, the drug *delayed* the appearance of but did not attenuate the magnitude of the major determinants of myocardial oxygen demand.

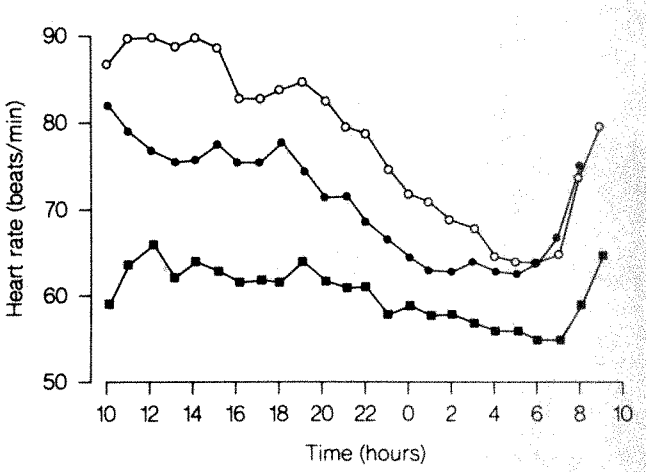

FIGURE 3. Twenty-four hour mean hourly heart rates for 22 patients on placebo, propranolol, 240 mg daily, and verapamil, 360 mg daily. Placebo therapy is indicated by **open circles,** propranolol therapy by **closed squares,** and verapamil therapy by **closed circles.** The **horizontal axis** shows clock time and the vertical axis indicates heart rate. Note the marked and consistent bradycardia produced by propranolol and the milder reduction in heart rate with verapamil.

Recent evidence suggests that these hemodynamic effects are the result of a complex interaction of verapamil's actions on systemic and coronary vessels.[34] Using the fixed doses employed in the present study, verapamil was superior to propranolol in prolonging exercise tolerance in patients with effort-related ischemic symptoms.

Comparison with previous placebo-controlled comparative studies: There have been 9 double-blind placebo-controlled randomized crossover clinical trials comparing verapamil with propranolol; this includes the results of the present trial (Table III). All trials evaluated the improvement in ischemia by both subjective (relief of anginal attacks and reduction of nitroglycerin consumption) and objective methods (exercise testing and, in some cases, Holter monitoring). All but 1 trial used fixed doses of both drugs; in some trials, 2 dose levels of 1 or both drugs were compared. Trials not utilizing a placebo-controlled double-blind design with objective end points are not considered in this report.

Sandler et al.[22] compared 4 weeks' therapy with verapamil in 2 dose levels (120 mg and 360 mg daily) with propranolol, 300 mg daily, in 16 patients with chronic stable angina pectoris. Only the higher dose of verapamil produced subjective and objective improvement in these patients; this was similar to that seen with propranolol. Liveseley et al.[23] compared 4 weeks' therapy with verapamil in 2 dose levels (240 mg and 360 mg daily) with propranolol (300 mg daily) and isosorbide dinitrate (60 mg daily) in 32 patients. The higher dose level of verapamil was similar to propranolol in relieving angina and in prolonging the duration of exercise; both agents were superior to low doses of verapamil and to nitrates. Fagher et al.[24] compared verapamil, 240 mg daily, to practolol, 300 mg daily, in a trial abbreviated because of reports of long-term toxicity with practolol. Although there was some benefit from therapy with verapamil (but not from practolol), the numbers of patients were too small to reach comparative conclusions.

Johnson et al.[25] compared 2 weeks of verapamil therapy to 2 weeks of propranolol therapy in 18 patients with effort-related angina pectoris. Each drug was given at 2 dose levels, each for 1 week: verapamil, 320 and 480 mg, and propranolol, 160 and 320 mg, and patients were evaluated by history, exercise testing, Holter monitoring, and radionuclide evaluation of ventricular function. The higher doses of both drugs attenuated the magnitude of S-T depression seen with exercise testing at a fixed workload, but verapamil was superior to propranolol in reducing the number of nitroglycerin tablets consumed and in reducing the number of episodes of S-T segment deviation on Holter monitoring. Neither drug produced clinically significant depression of left ventricular performance; propranolol caused a deterioration of pulmonary function, but verapamil did not. Sadick et al.[26] recently confirmed these findings; they compared 3 weeks of therapy with verapamil, 320 mg daily, to propranolol, 320 mg daily, in an independent study of 18 patients. Both drugs were equally effective in prolonging exercise tolerance; both drugs caused mild *decreases* in radionuclide ejection fraction at rest but mild *increases* in ejection fraction on effort.

Three recent studies found verapamil superior to propranolol in improving exercise tolerance in patients with angina of effort. Leon et al.[27] compared the efficacy of verapamil in a dose of 480 mg per day with doses of propranolol, 160 to 320 mg/day, individually titrated to produce an optimal clinical response. Verapamil was more effective than propranolol in increasing exercise time; however, patients were selected for this trial because they remained symptomatic on beta-blocker therapy; thus these investigators probably evaluated a patient population that was relatively resistant to propranolol. Frishman et al.[28] compared increasing doses of verapamil, 240, 320, and 480 mg daily, and propranolol, 60, 160, and 320 mg daily, in 20 patients with stable angina of effort; both drugs produced comparable relief of anginal symptoms and both agents increased exercise duration, but the improvement in exercise tolerance was greater with verapamil. Arnman and Ryden[29] compared verapamil, 360 mg daily, with metoprolol, 320 mg daily, in 24 patients; again, verapamil was superior to propranolol in improving exercise tolerance.

Clinical implications and conclusions: As a result, there is overwhelming evidence that verapamil produces subjective and objective relief of effort-related anginal symptoms in patients with ischemic heart disease to a degree comparable to that seen with beta-blocking agents. Although in many of these trials the duration of exercise was increased to a greater degree with verapamil than with propranolol, the differences between the two drugs were small. Furthermore, since all of the reviewed trials (except one) used a fixed-dose regimen for both agents, the greater effects seen with verapamil in some trials may have been abolished had the doses of the beta-blocking agent in these studies been individually titrated. Consequently, it is difficult to conclude that verapamil is superior to propranolol in patients with effort-related symptoms. Some patients clearly preferred and/or benefitted from one drug over the other, and their preference or benefit could not be predicted before a therapeutic trial with each agent. Hence, it is likely that the choice of a first-line agent for a given patient with ischemic heart disease will be dictated by considerations other than drug effectiveness, that is, by contraindications that exist before therapy or by adverse reactions that result after a therapeutic trial with a specific agent.

In conclusion, these results confirm that verapamil is comparable in efficacy to beta-adrenergic blocking drugs in the treatment of chronic stable angina; both agents are well tolerated, and neither significantly affects left ventricular performance.

The relative efficacies of oral verapamil, a calcium-entry blocking drug, and propranolol, a beta-adrenergic blocking drug, were compared in 12 patients who had both stable angina pectoris and mild to moderate systemic hypertension, using a placebo-controlled, double-blind, randomized crossover protocol. Compared with placebo, both propranolol and verapamil decreased the frequency of anginal attacks and the number of nitroglycerin tablets consumed, and increased exercise duration and total work; there were no significant differences in the antianginal effect of the two drugs. Both verapamil and propranolol reduced the supine and standing systolic and diastolic blood pressure measured at rest; compared with propranolol, however, verapamil had greater effects on standing diastolic blood pressure ($p < 0.002$). Resting heart rate was reduced from placebo baseline with large doses of both drugs; compared with verapamil, however, propranolol exerted greater effects on resting heart rate and rate-pressure product. Plasma renin activity was increased from placebo baseline with verapamil ($p < 0.05$), but was reduced with propranolol ($p < 0.05$); no significant change in plasma aldosterone was seen with either drug. Verapamil appears to be a safe and effective treatment alternative to propranolol for relieving anginal symptoms, improving exercise tolerance, and reducing elevated systemic blood pressure in patients with both angina pectoris and mild to moderate systemic hypertension.

Verapamil is a calcium-channel blocking drug which has proved useful in the treatment of patients with supraventricular tachyarrhythmias,[1,2] angina pectoris of effort,[3–5] vasospastic angina,[6–8] and hypertrophic cardiomyopathy.[9] Experimental and clinical studies have documented that verapamil can dilate the coronary and peripheral arteries by interfering directly with transmembrane calcium flux.[10] Such systemic vasodilating effects are likely responsible for the effectiveness of the drug in effort-related angina[4]; however, these effects on peripheral resistance suggest that verapamil and other calcium-entry blockers may also be effective in the management of patients with systemic arterial hypertension.[11]

Intravenous verapamil and sublingual nifedipine produce prompt and profound decreases in systemic blood pressure, and thus may be useful in the rapid treatment of hypertensive crises.[12,13] Long-term oral verapamil produces sustained antihypertensive responses in patients with established systemic hypertension.[14–19] However, few studies have compared verapamil with other antihypertensive agents,[15] and no studies have evaluated its efficacy in patients with both hypertension *and* angina pectoris.

* Value after 2 weeks of placebo treatment.
BP = blood pressure (mm Hg); MI = myocardial infarction; S-T↓ = S-T segment depression (mm).

Since propranolol, a beta-adrenergic blocking drug, is widely used in the management of patients with systemic hypertenstion and with angina pectoris,[20] a comparison of verapamil and propranolol is in order. Accordingly, using data obtained from a previous placebo-controlled, double-blind, randomized crossover trial,[4] we compared the antihypertensive and antianginal effects of verapamil and propranolol in a group of patients with both stable angina pectoris and systemic arterial hypertension.

Methods

Patient selection: Twelve ambulatory patients (11 men and 1 woman) with stable angina pectoris and mild to moderate systemic hypertension were entered into the study after written and informed consent was obtained. The patients represented a subgroup from a previously reported trial,[4] and their characteristics are shown in Table I. The mean patient age was 57.4 years (range 42 to 69). The diagnosis of angina pectoris was established by clinical history (at least 3 attacks/week of angina of effort for 3 months with no evidence of an accelerated course), response to nitroglycerin, and the development of typical symptoms with exercise testing. In addition, each patient demonstrated an abnormal response on two occasions to a standardized, multistage, treadmill exercise test, with at least 1 mm of flat or downward sloping S-T segment depression, 0.08 second after the J point. The diagnosis of coronary artery disease was made on the basis of coronary angiography (75% luminal narrowing of at least 1 major coronary vessel) in 5 patients, previous myocardial infarction in 3 patients, and an ischemic electrocardiographic response to exercise in the other 4 patients. No patient had previous coronary artery bypass surgery.

Systemic hypertension was documented in all patients by an average 3 minute standing diastolic blood pressure of 90 to 110 mm Hg (using Korotkoff phase V) on at least two separate outpatient visits while the patient was receiving no treatment.

Experimental design: During the study, patients were permitted sublingual nitroglycerin tablets (0.6 mg) as the only antianginal medication other than the test drugs. Nitroglycerin tablets were used as needed to treat anginal episodes and were not used prophylactically. Digitalis, propranolol, long-acting nitrates, and antiarrhythmic drugs were withdrawn at least 2 weeks before study entry. Patients received no additional antihypertensive therapy during the trial.

The blinded protocol (Fig. 1) consisted of an initial 2 week single-blind placebo run-in period.[4] During this time each patient received a placebo verapamil tablet (identical to an 80 mg tablet) and a placebo propranolol capsule (identical to an opaque gelatin capsule used throughout the study) every 8 hours. Patients who fulfilled all the inclusion criteria at the end of the second placebo run-in week entered the first drug treatment phase. During this phase, each patient received weekly increasing doses of either verapamil (240 mg/day, 80 mg every 8 hours; 320 mg/day, 80 mg every 6 hours; 480 mg/day, 120 mg every 6 hours) or propranolol (60 mg/day, 20 mg every 8 hours; 160 mg/day, 40 mg every 6 hours; 320 mg/day, 80 mg every 6 hours) over a 3 week titration period. After the

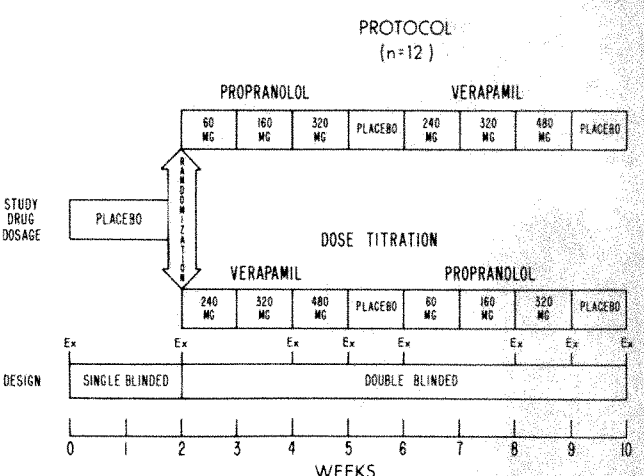

FIGURE 1. Propranolol-verapamil study design: a 2 week single-blind placebo phase, a double-blind randomization into propranolol and verapamil treatment groups, and a 3 week dose-titration phase. After a 1 week withdrawal schedule onto placebo, patients were crossed over to the other treatment schedule for a 3 week dose-titration phase, followed by a 1 week withdrawal schedule onto placebo. Standardized multistage graded exercise tests were performed at the times indicated by **Ex.** Study drug doses are indicated for the dose-titration phases.

TABLE II Effects of Placebo, Propranolol, and Verapamil on Resting Heart Rate and Blood Pressure (BP) in Patients With Angina Pectoris and Hypertension

	Baseline (Placebo)	Propranolol (320 mg/day)	Verapamil (480 mg/day)	Statistical Significance: Placebo vs Propranolol	Statistical Significance: Placebo vs Verapamil	Statistical Significance: Propranolol vs Verapamil
Supine						
Heart rate (beats/min)	80.0 ± 14.2	61.8 ± 7.3	71.6 ± 10.2	p <0.05	NS	p <0.02
Systolic BP (mm Hg)	158.3 ± 26.6	138.0 ± 17.7	144.3 ± 21.0	p <0.05	NS	NS
Diastolic BP (mm Hg)	97.5 ± 6.3	84.5 ± 10.8	87.9 ± 9.4	p <0.05	p <0.05	NS
Rate-pressure product × 10^2 (beats × mm Hg/min)	125.6 ± 25.1	85.0 ± 12.4	103.5 ± 21.4	p <0.05	p <0.05	p <0.01
3 minute standing						
Heart rate (beats/min)	89.7 ± 18.1	63.9 ± 9.7	77.6 ± 10.8	p <0.01	p <0.05	p <0.001
Systolic BP (mm Hg)	154.3 ± 21.5	139.0 ± 23.2	138.7 ± 19.9	NS	NS	NS
Diastolic BP (mm Hg)	100.3 ± 6.3	93.8 ± 11.3	86.6 ± 11.7	NS	p <0.05	p <0.002
Rate-pressure product (beats × mm Hg/min)	137.2 ± 27.0	88.9 ± 19.6	107.7 ± 21.7	p <0.01	p <0.05	p <0.001

NS = not significant.

initial dose titration, the patients underwent a 3 day down-titration phase, during which the amount of medication was decreased approximately 33% per day. The patients then entered a 5 to 7 day placebo period. After completion of this second placebo period, each patient crossed over to the other medication regimen and the dose titration, down-titration, and placebo phases were repeated.

Clinical observations: All patients kept a detailed daily record of anginal attacks and nitroglycerin tablets consumed. Blood pressure and heart rate determinations were made weekly at the same time of the day, 1 to 2 hours after ingestion of placebo or the experimental durg, which is the time of peak pharmacologic activity of propranolol and verapamil.[21]

Exercise tests: Each patient underwent serial exercise tests at visits 1, 2, 4, 5, 6, 8, 9, and 10 (Fig. 1); data from all visits except visit 1 were used for analysis. Multistage treadmill exercise testing consisted of identical sequential 3 minute stages of increasing workload, speed, and elevation using the Bruce protocol.[22] Tests were performed at approximately the same time and same day of the week for each patient. All patients were in the postabsorptive state and had ingested all study medication 1.0 to 2.5 hours before each test.

During exercise, blood pressure was measured every 3 minutes and lead V_5 was continuously monitored on an oscilloscope. The end point of exercise was the onset of angina, severe S-T segment changes of 4 mm or greater in the absence of anginal pain, a significant decrease in systolic blood pressure during exercise, the development of severe ventricular dysrhythmia (3 consecutive premature ventricular complexes), the occurrence of left bundle branch block, or a high degree of atrioventricular block.

Measurements of heart rate, systolic and diastolic blood pressure, S-T segment displacement, arrhythmia, and rate-pressure product (systolic blood pressure × heart rate) were taken at the last minute of each stage of exercise. At the end point of exercise, each test was also analyzed for the maximal

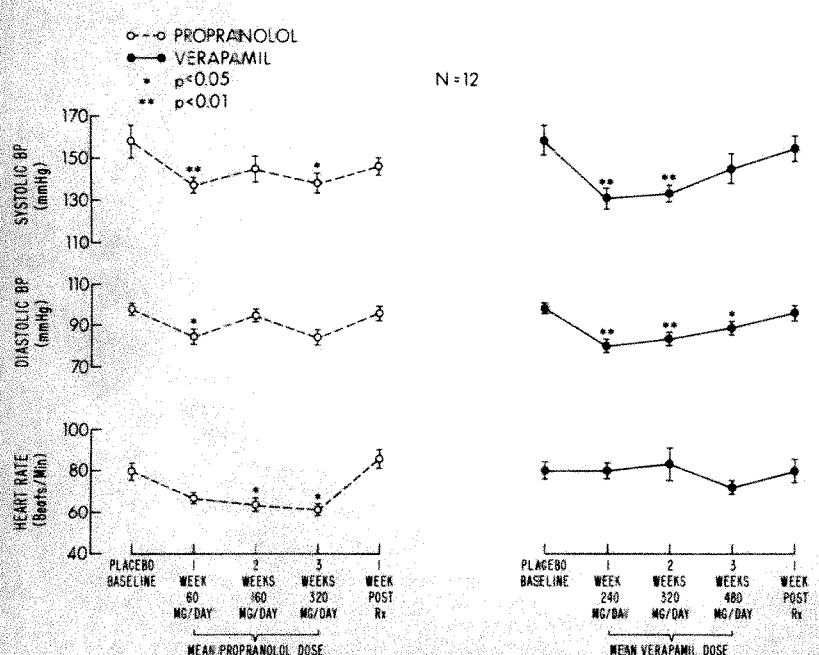

FIGURE 2. Supine blood pressure (BP) and heart rate at rest before, during, and after treatment with increasing doses of oral propranolol and verapamil. Comparisons are made with placebo baseline. Data are shown as mean ± standard error of the mean. Rx = treatment.

heart rate, systolic blood pressure and rate-pressure product achieved, total exercise duration (seconds), S-T segment displacement (mm), and reason for exercise limitation. The exercise work, expressed in kilopond-meters (kpm) was calculated from the formula: Work (kpm) = sin α × speed (m/s) × body weight (kg) × exercise time (seconds) divided by 10^3, where α is the angle of inclination of the treadmill.

Echocardiographic methods: Serial M-mode echocardiography was performed in the supine position in each patient, using a Picker echocardiograph (model 80 C) and a 2.25 MHz 13 mm diameter transducer. The transducer location and examination position were kept constant in all patients, allowing serial comparisons.

The left ventricular end-diastolic (LVd) and end-systolic (LVs) dimensions were measured at the Q wave of the electrocardiogram and at the time of minimal left ventricular diameter, respectively. Care was taken to assess these indexes at the maximal left ventricular dimension recorded and in a consistent relation to mitral valve landmarks. Left ventricular (LV) ejection time was taken as the interval from the Q wave to left ventricular end-systole minus 50 ms. Left ventricular volumes were calculated according to the method of Teichholz et al.[23] The ejection fraction was obtained by subtracting the end-systolic from the end-diastolic volume and dividing this value by the end-diastolic volume. The velocity of circumferential fiber shortening (Vcf) was calculated as (LVd − LVs)/(LVd × LV ejection time).

Plasma renin activity and aldosterone: Peripheral blood was obtained for measurement of plasma renin activity and plasma aldosterone during placebo therapy (visit 2) and during the highest dose levels of both verapamil (visit 5 or 9) and propranolol (visit 5 or 9). Blood was obtained, after an overnight fast, through an indwelling peripheral catheter after the patient had been upright for 2 hours. The samples were withdrawn into a chilled tube of ethylenediamine tetraacetic acid (EDTA). Plasma renin activity was determined by radioimmunoassay using the angiotensin II Immutope kit (Squibb). Plasma aldosterone levels were determined by radioimmunoassay using the aldosterone radioimmunoassay kit (International CIS). Twenty-four hour urinary collections were obtained for total volume, sodium, and potassium at the time of the plasma renin and plasma aldosterone determinations.

Propranolol, verapamil, and norverapamil levels: Blood for propranolol, verapamil, and norverapamil levels were obtained at weekly intervals during the placebo propranolol treatment, verapamil treatment, and drug withdrawal periods. The concentrations of propranolol in plasma were measured using the method of Coltart and Shand.[24] Verapamil and norverapamil levels were measured by liquid chromatographic analysis using the method of Harapat and Kates.[25]

Statistical analysis: Group data are expressed as mean ± standard deviation in the text and as mean ± standard error of the mean in the figures. In comparing the effects of each drug at different doses with placebo baseline values, a modified Fisher least significant difference test was employed. In comparing the effects of verapamil and propranolol, significance was determined for all variables (except renin and aldosterone) based on the difference from baseline values; a two-way analysis of variance was then used to determine whether there was a significant difference between the effects of the drugs. For renin and aldosterone data, because of the large variability of the data, a nonparametric sign test was used. Differences were considered significant if the p value was less than 0.05.

Results

Dropouts and drug compliance: All 12 patients who entered the study completed the trial and were titrated to dose levels of 320 mg/day of propranolol and 480 mg/day of verapamil. Drug compliance (determined by medication counts) for the 3 placebo phases and the 2 drug treatment phases was 95 ± 12%. Plasma drug levels also confirmed patient compliance since a linear relation was seen between dose and plasma level as the drug dose was increased.

Effects on resting blood pressure and heart rate (Table II, Figs. 2 and 3): Verapamil therapy caused a significant reduction from placebo to baseline in supine and standing systolic blood pressure with 320 mg daily

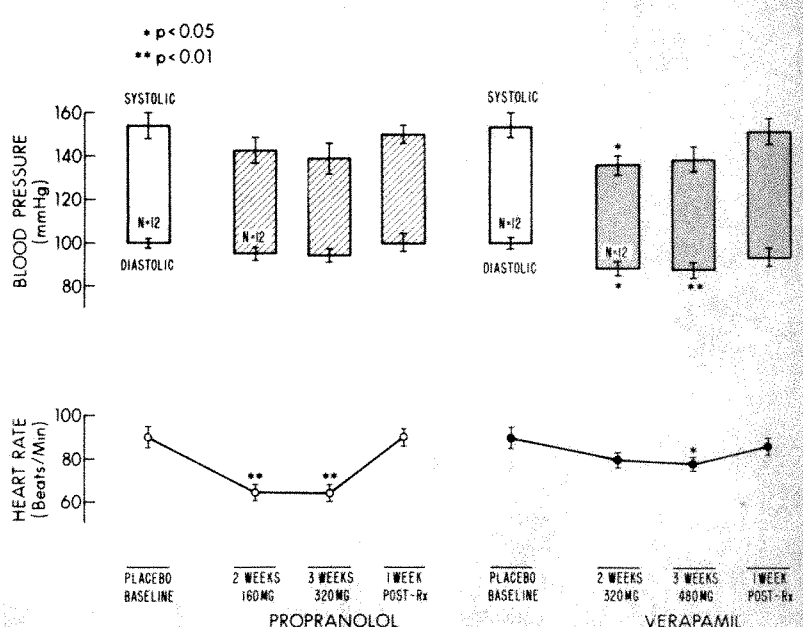

FIGURE 3. Standing blood pressure and heart rate at rest before, during, and after treatment with increasing doses of oral propranolol and verapamil. Comparisons are made with placebo baseline. Data are shown as mean ± standard error at the mean. Rx = treatment.

TABLE III Effects of Placebo, Propranolol, and Verapamil on Anginal Symptoms, Exercise Tolerance, and Exercise Variables

	Baseline (Placebo)	Propranolol (320 mg/day)	Verapamil (480 mg/day)	Statistical Significance: Placebo vs Propranolol	Placebo vs Verapamil	Propranolol vs Verapamil
Angina results						
Attacks/week	12.7 ± 10.5	4.2 ± 6.6	2.0 ± 2.0	$p < 0.01$	$p < 0.01$	NS
NTG consumption/week	8.6 ± 14.4	1.9 ± 4.3	0.9 ± 1.7	NS	NS	NS
Stress test results						
Exercise duration (s)	318.5 ± 113.0	454.1 ± 127.6	485.4 ± 137.4	$p < 0.05$	$p < 0.01$	$p < 0.04$
Exercise work (kpm/10^3)	2.6 ± 1.5	4.6 ± 2.4	5.1 ± 2.6	$p < 0.05$	$p < 0.01$	NS

BP = blood pressure; NS = not significant; NTG = nitroglycerin; S-T↓ = S-T segment depression.

of the drug ($p < 0.01$) but not with 480 mg daily; a dose of 240 mg daily reduced supine systolic pressure ($p < 0.01$) without affecting standing pressure. Verapamil reduced supine and standing diastolic blood pressure at all dose levels ($p < 0.01$ and $p < 0.05$). The best overall blood pressure-lowering effect occurred with 320 mg of verapamil daily, although some patients responded best with higher and lower doses.

Propranolol treatment caused an insignificant reduction from placebo baseline in standing systolic and diastolic blood pressure at all dose levels, but a significant reduction in supine systolic ($p < 0.01$) and diastolic pressure ($p < 0.05$) with 60 mg/day; only supine systolic blood pressure was significantly reduced by 320 mg daily of propranolol ($p < 0.05$). The hypotensive effects of the two drugs did not differ significantly; verapamil, however, produced a greater reduction in standing diastolic blood pressure than did propranolol ($p < 0.002$).

In this study, normalization of blood pressure was defined as a standing diastolic blood pressure of less than 90 mm Hg that was also reduced by at least 10 mm Hg from the baseline value. Eleven of 12 patients had normalization of blood pressure on verapamil, and 7 of 12 responded to propranolol.

Verapamil caused a significant reduction in heart rate only at the highest dose, 480 mg/day, and only for standing heart rate, $p < 0.05$. Propranolol caused a significant reduction in both supine and standing heart rates at the 160 mg and 320 mg/day doses ($p < 0.05$ and $p < 0.01$, respectively). The effects of propranolol on heart rate were more pronounced than those seen with verapamil (supine heart rate, $p < 0.02$; standing heart rate, $p < 0.001$).

Effects on exercise variables (Table III, Fig. 4): The change in rate-pressure product from rest to stage I was significantly reduced by both propranolol and verapamil (both $p < 0.05$); the change in rate-pressure

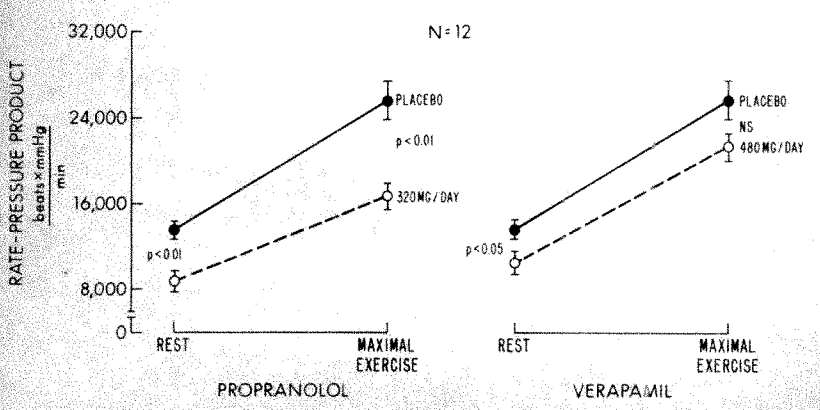

FIGURE 4. Comparative effects of placebo, propranolol, and verapamil on rate-pressure product at rest and during maximal exercise. **Solid lines** indicate placebo therapy; **dashed lines** indicate the effects of active drug therapy. Values are mean ± standard error of the mean. NS = not significant.

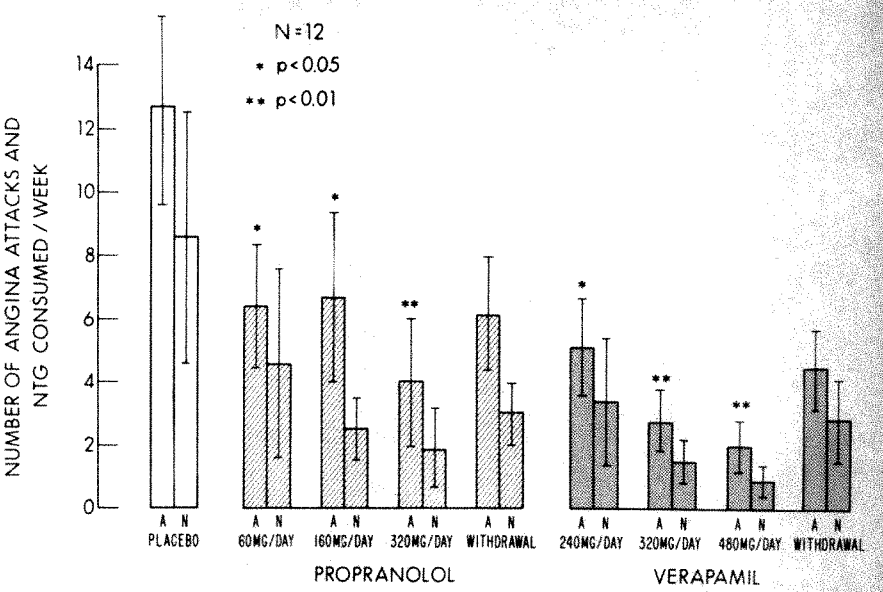

FIGURE 5. Weekly frequency of angina pectoris attacks (A) and nitroglycerin (NTG) consumption (N) before, during, and after treatment with increasing doses of oral propranolol and verapamil. Comparisons are made with placebo baseline. Data are shown as mean ± standard error of the mean.

product from rest to stage II was reduced only by propranolol ($p < 0.05$) and not by verapamil. At maximal exercise, heart rate, systolic blood pressure, and rate-pressure product were significantly lower with propranolol ($p < 0.01$), but these variables were not affected by verapamil; the changes seen with propranolol were significantly greater than those seen with verapamil ($p < 0.01$).

Effects on angina pectoris and exercise-induced ischemia (Table III, Fig. 5): There was a significant reduction in the number of anginal attacks per week reported in patient diaries with both drugs at all dose levels. The optimal antianginal effects appeared at the highest dose levels of both drugs; there was no difference in the magnitude of improvement in angina seen with verapamil and propranolol.

Verapamil and propranolol did not reduce the magnitude of S-T segment depression at maximal exercise seen during placebo therapy. At submaximal exercise, despite a higher rate-pressure product with verapamil than with propranolol, the degree of S-T segment depression was greater with propranolol than with verapamil.

Four patients demonstrated an arrhythmia during the placebo baseline exercise test: 2 patients had unifocal premature ventricular complexes during exercise that were eliminated by propranolol and verapamil but returned upon withdrawal of both drugs, 1 patient had frequent premature ventricular complexes and ventricular bigeminy during exercise that were not affected by either propranolol or verapamil, and 1 had frequent atrial premature contractions that were completely eliminated by propranolol and verapamil treatment. No patient manifested new or enhanced arrhythmias while receiving verapamil and propranolol.

Exercise tolerance (Table III, Fig. 6): Significant increases in total exercise time and calculated exercise work were demonstrated with both propranolol (160 and 320 mg/day) and verapamil treatment (320 and 480 mg/day). The mean overall improvement was greatest at the highest dose levels. Verapamil was more effective in improving exercise time than propranolol ($p < 0.04$).

Effects on echocardiographic indexes of left ventricular function (Table IV): Neither drug altered end-diastolic or end-systolic volumes, ejection fraction, or the velocity of circumferential fiber shortening.

Plasma drug levels: There was a linear relation between the plasma level of propranolol and the drug dose ($r = 0.60$). The plasma concentrations found after 60, 160, and 320 mg of propranolol/day were 33.4 ± 39.9, 84.7 ± 69.4, and 162.7 ± 98.3 ng/ml, respectively. There was also a linear relation between drug dose and the plasma levels of verapamil and its active metabolite, norverapamil ($r = 0.54$, $r = 0.52$). The concentrations found after 240, 320, and 480 mg/day of verapamil were

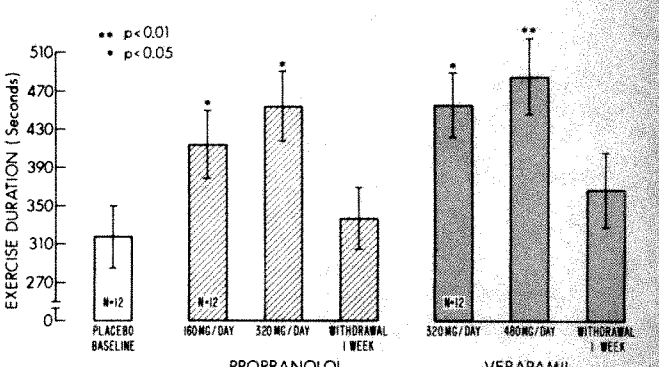

FIGURE 6. Treadmill exercise duration before, during, and after treatment with increasing doses of oral propranolol and verapamil. Comparisons are made with placebo baseline. Values are shown as mean ± standard error of the mean.

TABLE IV Effects of Placebo, Propranolol, and Verapamil on Echocardiographic Indexes of Left Ventricular Function

	Placebo	Propranolol (320 mg/day)	Verapamil (480 mg/day)
End-diastolic volume index (ml/m^2)	64.9 ± 14.5	69.2 ± 18.7	68.9 ± 16.2
End-systolic volume index (ml/m^2)	29.8 ± 15.3	29.8 ± 12.2	30.3 ± 15.1
Ejection fraction (%)	56.1 ± 14.7	58.0 ± 9.0	57.9 ± 12.7
Velocity of circumferential fiber shortening (circ/s)	1.03 ± 0.26	0.96 ± 0.20	1.03 ± 0.24

141.5 ± 82.4, 218.8 ± 129.7, and 315.9 ± 107.7 ng/ml, respectively; for norverapamil, 136.6 ± 50.4, 179.9 ± 70.2, and 252.7 ± 57.9, respectively. There was no relation between plasma drug levels of propranolol or verapamil and clinical responses to these drugs (blood pressure- and heart rate-lowering effects, effects on exercise tolerance, reduction in anginal attacks).

Plasma renin and aldosterone levels (Fig. 7): Compared with placebo (111.4 ± 128.7 ng/100 ml/h), plasma renin activity was significantly reduced by propranolol (56.9 ± 117.8 ng/100 ml/h, $p < 0.05$), but increased during treatment with verapamil (291.3 ± 338.7 ng/100 ml/h, $p < 0.05$); the effects of the two drugs on plasma renin activity differed significantly ($p < 0.01$). There was no relation between the changes in plasma renin activity with propranolol or verapamil and the magnitude of the decrease in blood pressure seen with the two drugs. There were no significant differences from placebo with verapamil or propranolol in the concentration of sodium or potassium excreted in the urine over 24 hours. Mean plasma aldosterone levels decreased slightly but not significantly with propranolol and increased, but not significantly, with verapamil (186.8 ± 96.9 pg/ml with placebo, 161.2 ± 110.9 pg/ml with propranolol, and 291.3 ± 338.7 pg/ml with verapamil).

Safety variables: No changes in body weight were noted with either verapamil or propranolol therapy. One patient complained of fatigue on propranolol, and another patient had constipation with verapamil. All routine screening blood tests, urinalyses, electrocardiograms (P-R intervals), and chest x-ray films remained unchanged during the study.

Discussion

Antihypertensive effects of verapamil: Although most of the interest surrounding the calcium-channel blocking drugs has centered on their use in the management of patients with angina pectoris[3–8] and supraventricular tachyarrhythmias,[1,2] these agents are also effective in the management of patients with hypertension.[11,26,27] Earlier experience with calcium antagonists in such patients focused on their parenteral use in hypertensive crises.[13,26,27] More recently, oral therapy with verapamil, nifedipine, and diltiazem has been reported to produce short-term decreases in systemic pressure in hypertensive patients[14–19,28,29]; the doses of verapamil used in these studies have ranged from 80 to 160 mg orally 3 or 4 times daily. However, there have been few studies comparing the effectivensss of verapamil with that of other antihypertensive agents.[15,30]

The results of this double-blind, placebo-controlled study demonstrate that verapamil is an effective antihypertensive agent in patients with both hypertension and angina pectoris. The drug significantly reduced resting systolic and diastolic blood pressure in the standing and supine positions at the lowest (240 mg/day) and highest doses (480 mg/day), but its greatest hypotensive effects were observed with 320 mg daily. The explanation for this partial loss of effectiveness with the highest verapamil dose is not known, but may be related to the partial development of drug tolerance (since doses of the drug were administered in an incremental sequence) or to the activation of counteractive forces (that is, the renin-angiotensin or sympathetic nervous system) with higher doses of verapamil, which may not occur with lower doses. Although propranolol also effectively lowered blood pressure in this study, verapamil was more effective in reducing standing diastolic blood pressure at rest. Postural hypotensive responses were not seen with either drug. Eleven of 12 patients had normalization of blood pressure with verapamil; 7 of 12 patients responded to propranolol.

Mechanism of hypotensive effects: The mechanisms underlying verapamil's antihypertensive effects are likely to be multifactorial. The drug is a potent peripheral vasodilator agent and therefore exerts hypotensive actions similar to those seen with other direct-acting vasodilator drugs. Therapy with most vasodilator agents is accompanied by sympathetically mediated reflex increases in heart rate and cardiac output, which tend to diminish their antihypertensive effectiveness and are often responsible for producing many of their adverse effects.[31] However, increases in heart rate and cardiac output do not generally accompany verapamil treatment[12] because the drug exerts direct depressant effects on sinoatrial automaticity and myocardial contractility.[32] Hence, the inherent limitations of traditional vasodilator therapy in the management of patients with systemic hypertension are not seen with verapamil. The mechanisms underlying verapamil's antihypertensive effects are different from those of beta-adrenergic blocking drugs like propranolol, which result in a decrease in heart rate and in cardiac output accompanied by little change or an increase in peripheral vascular resistance.[33,34] Propranolol but not verapamil attenuates the increases in systolic blood pressure during exercise; this is likely the result of blockade of exercise-induced activation of the sympathetic nervous system by propranolol, which does not occur with verapamil.

Beta-blocking drugs may exert their antihypertensive effects in part by decreasing plasma renin activity and

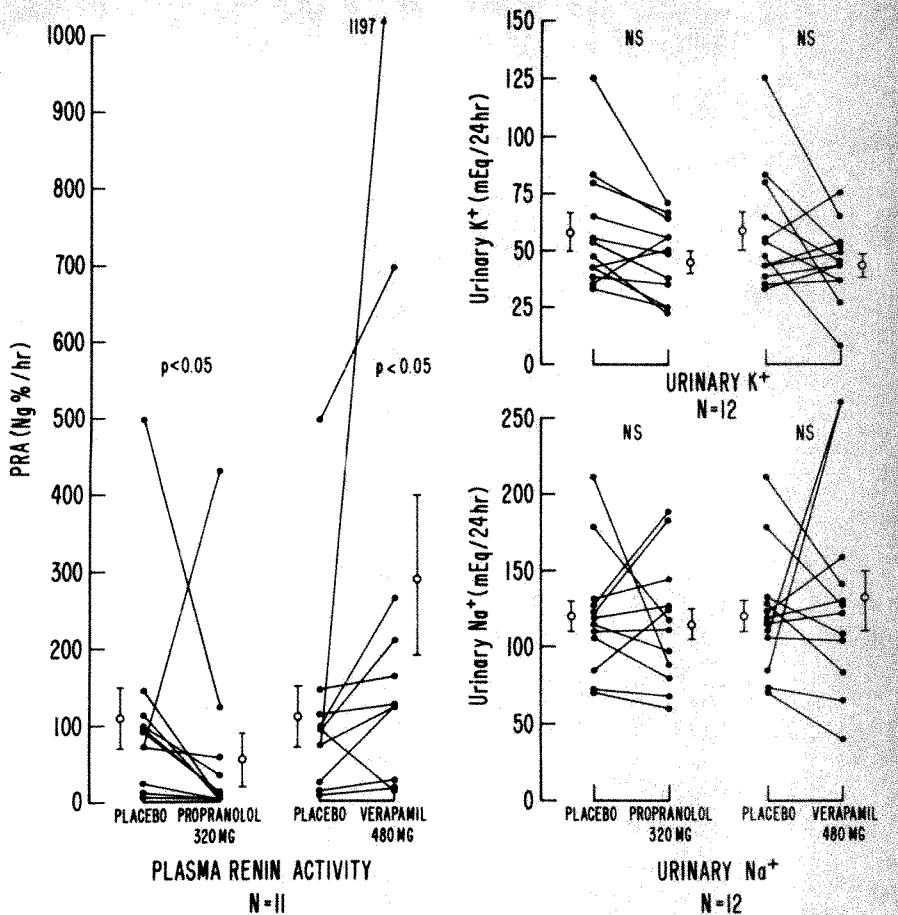

FIGURE 7. Effects of placebo, propranolol, and verapamil on 24 hour excretion of urinary electrolytes and plasma renin activity (PRA). The **closed circles** represent individual patient measurements; the **open circles** indicate mean values ± standard error of the mean.

plasma aldosterone.[35] In contrast, the hypotensive effects of vasodilator antihypertensive drugs are accompanied by an increase in plasma renin activity,[36,37] and our results indicate that verapamil (480 mg/day) does not differ from other vasodilator drugs in this regard; such increases are similar to those seen with large doses of nifedipine.[38] It is possible that the increases in plasma renin activity with 480 mg doses of verapamil serve to counteract the hypotensive effects of the drug, since the decreases in blood pressure were greater with 320 mg than with 480 mg of the drug; however, we did not measure changes in plasma renin activity with lower doses of verapamil. Despite the elevation in plasma renin activity with verapamil treatment, we observed no decrease in urinary sodium excretion and no gain in weight during either of the double-blind treatment periods.

Effects on angina and exercise tolerance: The effectiveness of verapamil in the management of patients with angina of effort and at rest has been shown in several placebo-controlled clinical trials.[3–8] Verapamil appears superior to propranolol in the treatment of patients with angina at rest[39] and is similar to propranolol in the management of patients with angina of effort.[4,40–42] In this study of 12 patients with both hypertension and angina pectoris, verapamil had a significantly greater effect on exercise tolerance than propranolol; however, the two drugs exerted similar effects on calculated exercise work, angina frequency, and nitroglycerin consumption. The maximal improvement in exercise tolerance and symptoms of angina were seen with higher doses of verapamil (480 mg daily) than those which achieved optimal control of blood pressure in these same patients.

At rest and at submaximal levels of exercise, both verapamil and propranolol produced a lower heart rate-blood pressure product than those seen during therapy with placebo. Hence, both drugs appear to exert their antianginal effects in part by reducing myocardial oxygen demands. However, for a given value of rate-pressure product, there was always more S-T segment depression with propranolol treatment than with verapamil therapy. Hence, verapamil appeared to exert antianginal effects in addition to its effects on myocardial oxygen consumption, possibly mediated by its direct effects on the coronary circulation.[43]

Relation between plasma drug levels and pharmacologic effects: Both verapamil and propranolol demonstrate first-pass hepatic metabolism when administered orally to patients with coronary artery disease.[27,44] This means that a substantial fraction of an oral dose will undergo hepatic biotransformation during the first pass through the liver and fail to reach the systemic circulation. Smaller doses may be completely metabolized with little residual drug reaching the systemic circulation, whereas larger doses can saturate the

hepatic enzyme systems and provide therapeutic blood levels. In this study, there was a linear relation between increments in the doses of both propranolol and verapamil and their respective plasma drug levels. Similar to findings with propranolol,[44] no relation was seen between verapamil plasma levels and its pharmacologic effects (on heart rate and blood pressure) in patients receiving the drug.

Clinical implications: In this study, verapamil was shown to be a safe and effective alternative to propranolol for reducing spontaneous attacks of angina pectoris, improving exercise tolerance, and reducing elevated blood pressure. Further double-blind studies investigating the long-term efficacy of verapamil and evaluating the use of verapamil in combination with other antihypertensive drugs (such as diuretics or beta-adrenergic blocking agents) need to be done. Verapamil provides a new conceptual approach to patients with both angina pectoris and systemic hypertension: calcium-entry blockade.

Acknowledgment

We express our sincere appreciation to Susan Kreitzer for her major technical contributions and to Nina Scotti for her valuable help in preparing the manuscript. The authors also thank Knoll Pharmaceutical Company, Whippany, New Jersey, for supplying verapamil.

Rationale for the Choice of Calcium Antagonists In Chronic Stable Angina

An Objective Double-Blind Placebo-Controlled Comparison of Nifedipine and Verapamil

V. BALA SUBRAMANIAN, MD, MICHAEL J. BOWLES, MRCP, NARDEV S. KHURMI, MBBS, ANTHONY B. DAVIES, MB, MRCP, and EDWARD B. RAFTERY, MD

The effectiveness and safety of verapamil, nifedipine, and placebo in patients with chronic stable angina pectoris were evaluated and compared in two double-blind randomized crossover trials. In the first study, nifedipine (10 mg 3 times daily) was compared with placebo in 24 patients with chronic effort-related angina pectoris; no significant differences in exercise performance were observed with nifedipine compared with placebo. In the second study, the effects of verapamil (120 mg 3 times daily), nifedipine (20 mg 3 times daily), and placebo were compared in 32 patients with chronic stable angina using a double-blind crossover study design. Compared with placebo, both nifedipine and verapamil prolonged exercise duration (5.7 ± 0.3 minutes with placebo, 7.9 ± 0.5 minutes with nifedipine [p <0.001], and 10.0 ± 0.7 minutes with verapamil [p <0.001]), but the improvement with verapamil was greater than that seen with nifedipine (p <0.01). Seven patients had increasing angina with nifedipine, none did with verapamil; the exacerbation of angina during nifedipine therapy appeared related to our observation that, compared with placebo, patients receiving nifedipine had higher heart rates, while patients receiving verapamil had slower heart rates. This study indicates that, at the doses used, verapamil was more effective and better tolerated than nifedipine in patients with chronic stable angina pectoris.

The role of calcium antagonists in the management of patients with chronic stable angina of effort is well established,[1,2] but little work has been done to compare the effectiveness and safety of the two most widely employed agents, verapamil and nifedipine. Verapamil was first introduced as a coronary vasodilator[3] and was later demonstrated to be an effective antiarrhythmic agent.[4] The drug was initially suspected to be a beta-adrenergic blocking agent,[3] but later work showed that its effects were mediated by calcium-channel blockade[5]; it has been used in the treatment of supraventricular tachyarrhythmias,[6] angina pectoris,[7] and hypertrophic cardiomyopathy.[8] Nifedipine was developed as a specific calcium-channel blocker and has been advocated as an effective drug in variant and effort-related angina pectoris.[9,10]

We conducted two randomized double-blind placebo-controlled crossover studies in patients with chronic stable angina pectoris. The first compared the effects of placebo and nifedipine (30 mg daily) in 24 patients; the second trial* compared the effects of verapamil (360 mg daily) with nifedipine (60 mg daily) and placebo in 32 patients. These studies show that, in the doses used in these studies, verapamil produces fewer adverse reactions and is superior to nifedipine in enhancing exercise performance in patients with effort-related angina pectoris.

Double-Blind Comparison of Placebo and Nifedipine

Patient Population

Twenty-four patients with chronic stable angina were entered into the first trial, after all previous antianginal medications had been withdrawn for at least 4 weeks. All patients had chest pain relieved by rest and by sublingual nitroglycerin and at least 1 mm horizontal S-T depression on standardized treadmill exercise testing. Patients with a recent myocardial infarction (within the last 4 months), with unstable or accelerating symptoms, with clinical congestive heart failure or

* This study was previously published.[11]

resting blood pressure over 160/100 mm Hg, or with insulin-dependent diabetes mellitus were excluded. No patient received digitalis, diuretics, or other cardiovascular agents before or during the study; the only medications permitted were the study drugs and sublingual nitroglycerin for anginal attacks.

Trial Design

This trial was a double-blind crossover study comparing placebo with nifedipine administered as 10 mg 3 times daily. Each drug was administered for 4 weeks with a 2 week crossover period between the study periods; only exercise testing was used for evaluation of the patients. All exercise tests were limited by angina, dyspnea, fatigue, or pain in the legs; all were performed in the morning 90 to 150 minutes after the last dose of the drugs and after 30 minutes of rest in a temperature-controlled laboratory. The details of the exercise testing procedure are reported elsewhere in this symposium.[12] Clinical efficacy and side effects were monitored closely. Statistical analysis was performed with a programmable calculator by the paired t test.

Results

Twenty-four patients entered this study, and 20 completed both placebo and active drug periods. The results are shown in Table I. There was no significant difference between placebo and nifedipine in a dose of 10 mg 3 times daily in any of the objective variables. Two patients were withdrawn due to uncontrolled angina while taking nifedipine.

TABLE I Comparative Effects of Placebo and Nifedipine, 30 mg Daily, in Patients With Chronic Stable Exertional Angina*

	Placebo	Nifedipine (10 mg tid)	p
Exercise time (min)	6.8 ± 0.6	6.9 ± 0.7	NS
1 mm time (min)	4.8 ± 0.7	4.6 ± 0.5	NS
ST↓ at peak effort (mm)	1.8 ± 0.2	1.7 ± 0.1	NS
Resting heart rate (beats/min)	74 ± 3	76 ± 3	NS
Maximal heart rate (beats/min)	129 ± 4	128 ± 4	NS

* Data are expressed as mean ± standard error of the mean. NS = not significant; ST↓ = S-T segment depression; tid = 3 times a day; 1 mm time refers to the duration of exercise until the appearance of 1 mm S-T segment depression.

Double-Blind Comparison of Nifedipine and Verapamil

Patient Population

Thirty-two patients with chronic stable angina entered the second trial. All patients had chest pain relieved by rest and by sublingual nitroglycerin and at least 1 mm horizontal S-T depression on standardized treadmill exercise testing. Patients with a recent myocardial infarction (within the last 4 months), with unstable or accelerating symptoms, with clinical congestive heart failure or resting blood pressure over 160/100 mm Hg, or with insulin-dependent diabetes mellitus were excluded. No patient received digitalis, diuretics, or other cardiovascular agents before or during the study; the only medications permitted were the study drugs and sublingual nitroglycerin for anginal attacks.

Trial Design

The second trial had 1 placebo and 2 active drug phases. After completion of an initial 2 week placebo run-in period, all patients entered a double-blind randomized crossover study consisting of 4 weeks of treatment with either nifedipine, 20 mg 3 times daily, or verapamil, 120 mg 3 times daily. At the end of 4 weeks, each patient received placebo for a 1 week washout period, after which the active drugs were crossed over, and each patient received 4 weeks of therapy with the alternate drug.

Exercise testing was repeated at the end of placebo, and after 4 weeks of each active drug therapy. All exercise tests were limited by angina, dyspnea, fatigue, or pain in the legs; all were performed in the morning 90 to 150 minutes after the last dose of the drugs and after 30 minutes of rest in a temperature-controlled laboratory. In addition, 24 hour ambulatory electrocardiographic monitoring with a frequency-modulated recorder was performed during each study period to establish changes in resting heart rate, directional changes in S-T segments, and the appearance of conduction defects. The details of the exercise testing and electrocardiographic monitoring procedures are reported elsewhere in this symposium.[12]

Statistical analyses were performed with a programmable calculator by t test for paired data.

Results

Of the 32 patients who entered the trial, 1 was withdrawn during placebo therapy due to detection of hypochromic anemia. Three patients were withdrawn within 3 days of the first leg of the crossover while receiving nifedipine. The remaining 28 patients completed 4 weeks of treatment with the first randomized drug (nifedipine in 13 and verapamil in 15). Two weeks after the crossover to nifedipine had been completed, 4 more patients (who had successfully completed the verapamil phase of the study) were withdrawn due to side effects; however, they completed all the evaluations while on treatment with nifedipine for 2 weeks. The data consist of variables from the 28 patients who completed all the tests.

Exercise duration (Fig. 1, Tables II and III: The duration of exercise during placebo therapy (5.7 ± 0.3 minutes) was prolonged by both nifedipine (7.9 ± 0.5 minutes, $p < 0.001$) and verapamil (10.0 ± 0.7 minutes, $p < 0.001$), but the improvement with verapamil was

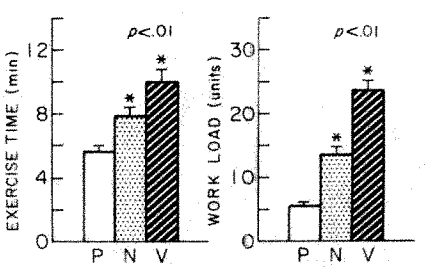

FIGURE 1. Duration of exercise (**left panel**) and workload (**right panel**) during therapy with placebo (P), nifedipine (N), and verapamil (V). Data are shown as means ± standard error of the mean. **Asterisks** indicate significance of differences between active drug therapy and placebo. P values indicate significance of differences between nifedipine and verapamil.

significantly greater than that with nifedipine ($p < 0.01$). All 28 patients stopped exertion during treadmill testing because of angina during the placebo phase, 20 stopped because of angina while taking nifedipine, and 17 patients had their exercise tests limited by angina while receiving verapamil. The exercise time with verapamil was longer than with nifedipine in 22 patients, shorter in 5 patients, and similar in 1 patient. The maximal workload achieved averaged 5.6 ± 0.4 units with placebo, 13.6 ± 0.9 units with nifedipine ($p < 0.001$ versus placebo), and 23.8 ± 1.2 units with verapamil ($p < 0.001$ versus placebo and $p < 0.001$ versus nifedipine).

Exercise variables and electrocardiographic S-T segment responses (Fig. 2, Table II): The time to 1 mm S-T segment depression during placebo therapy (3.9 ± 0.3 minutes) was prolonged by both verapamil and propranolol, but the improvement with verapamil (7.1 ± 0.5 minutes) was significantly greater than that with nifedipine (5.8 ± 0.4 minutes) ($p < 0.01$); this was true as well for the time to 2 mm S-T depression. At the same workload achieved during placebo therapy, both nifedipine and verapamil reduced the magnitude of S-T depression, but the improvement seen with verapamil was greater ($p < 0.05$). However, the magnitude of S-T

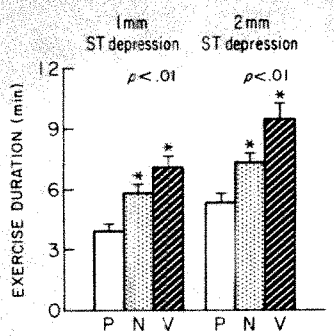

FIGURE 2. Time on a treadmill exercise test to the development of 1 and 2 mm S-T depression during treatment with placebo (P), nifedipine (N), and verapamil (V). Data are shown as means ± standard error of the mean. **Asterisks** indicate significance of differences between active drug therapy and placebo. P values indicate significance of differences between nifedipine and verapamil.

depression at maximal exercise was unchanged by both drugs; this S-T depression, however, was seen after a longer duration of exercise with both nifedipine and verapamil. Neither drug significantly altered the double-product at peak effort.

Compared with placebo (74 ± 2 beats/min), heart rate decreased with verapamil (68 ± 2 beats/min, p <0.001), but did not change with nifedipine (77 ± 2 beats/min). The heart rate at the same workload achieved at peak effort during placebo therapy was reduced by both drugs, but the effects of verapamil were more pronounced (p <0.001). Nifedipine *increased* the heart rate observed at peak effort (p <0.001); this was not altered by verapamil.

Twenty-four hour ambulatory monitoring (Fig. 3 and 4): The pooled mean hourly heart rate on placebo, verapamil, and propranolol was related to clock time and expressed as a continuous curve. Verapamil reduced heart rate throughout the day, but heart rate was increased with nifedipine (Fig. 3). The mean number of minutes during which the heart rate exceeded 100 beats/min was 101 ± 10 minutes with nifedipine, which was significantly higher than that with placebo (42 ± 5 minutes); both were higher (p <0.001) than that during therapy with verapamil (4 ± 1 minutes). The number of episodes (in 24 hours) of S-T depression greater than 1 mm was 15 ± 2 on placebo; this remained unchanged with nifedipine but was markedly reduced by verapamil (9 ± 2, p <0.001) (Fig. 4).

Adverse reactions (Table III): During verapamil therapy, no patient exhibited evidence of congestive heart failure or atrioventricular conduction disturbance. After 2 weeks on verapamil, one patient developed mild pedal edema which responded to therapy with diuretics. Minor side effects included constipation in 6 patients, headache in 2, and giddiness in 1. None required withdrawal of treatment.

In contrast, major adverse effects were observed during treatment with nifedipine. Three patients had to be withdrawn from the trial during the nifedipine phase before completing 2 weeks of treatment: one patient had unstable angina, which required intraaortic balloon pumping for relief; another patient had severe muscular weakness and tremor, which disappeared within 24 hours after withdrawal of nifedipine; and the third patient had ankle edema, palpitations, angina, and severe headache. Four other patients were withdrawn from nifedipine after completing 2 weeks of therapy because of palpitations, headaches, and angina provoked by nifedipine ingestion. The Holter monitoring record in one of these patients is shown in Figure 5. This patient had a rapid increase in heart rate which began 45 minutes after ingestion of the drug and persisted for about 1 hour; this was accompanied by S-T segment depression and angina. Minor side effects during treatment with nifedipine, which did not necessitate withdrawal, including flushing, tremors, mild pedal edema, and palpitations.

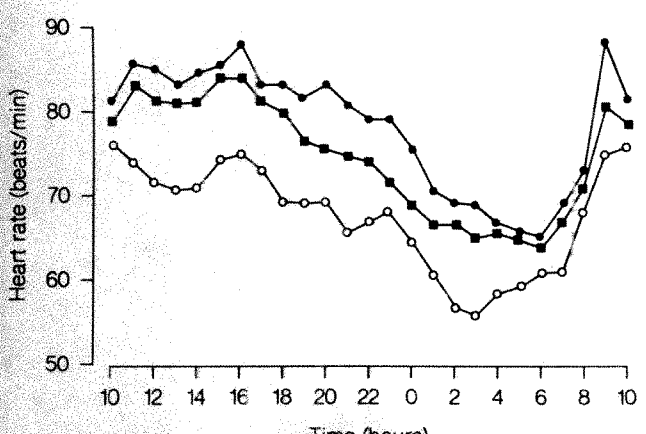

FIGURE 3. Pooled hourly mean heart rates of 28 patients taking placebo (**solid squares**), verapamil (**open circles**), and nifedipine (**solid circles**). Note the higher hourly mean heart rates with nifedipine and the lower heart rate during therapy with verapamil.

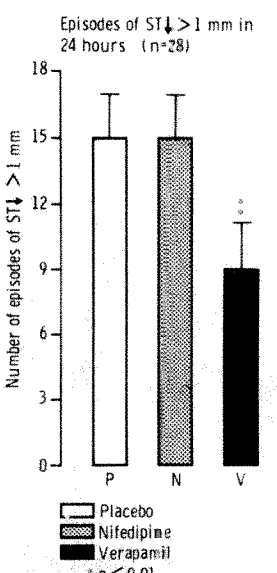

FIGURE 4. The mean number of episodes of S-T depression (ST↓) in 24 hour treatment with placebo (P), verapamil (V), and nifedipine (N). Only verapamil produced a significant reduction in the number of episodes.

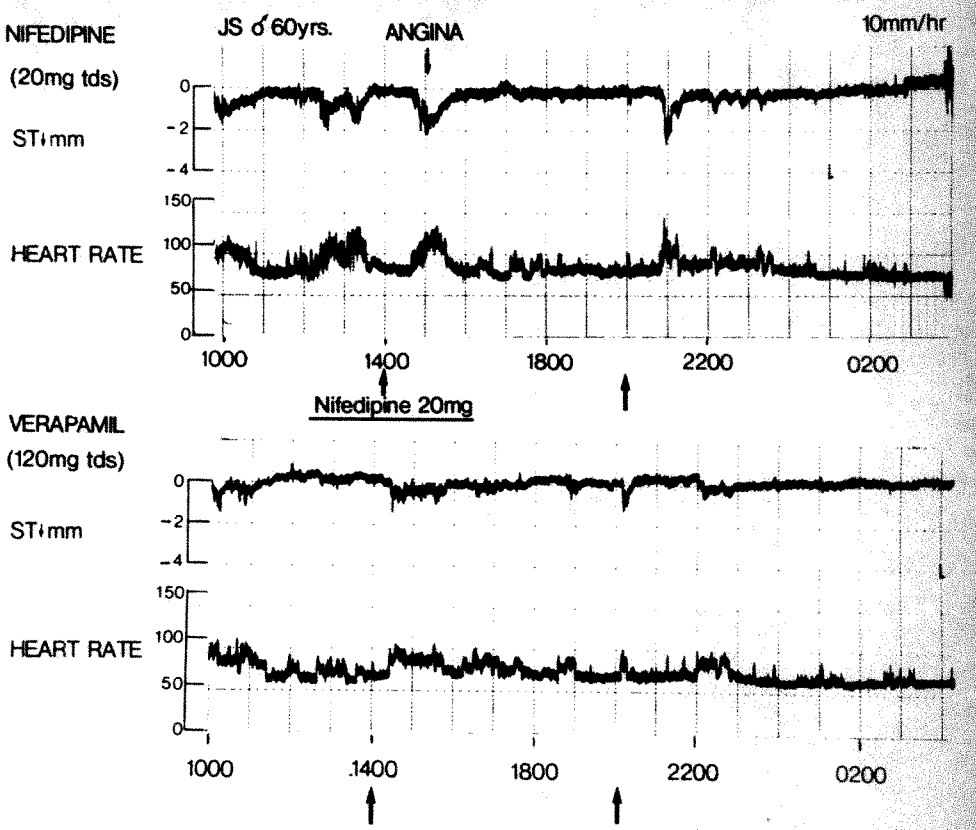

FIGURE 5. Twenty-four hour ambulatory heart rate and S-T segment trend of a patient who had angina after nifedipine and withdrew from the trial after 2 weeks of the nifedipine phase. The **top channel** of both trends shows calibrated S-T segment levels and the **bottom channel** shows the heart rate. Clock time is shown on the **horizontal axis**. The times of verapamil and nifedipine ingestion are marked by the **upright arrows** at 1400 and 2000 hours. Note the increase in heart rate within 45 minutes of nifedipine administration, accompanied by marked S-T segment depression and angina; similar episodes of S-T segment depression and angina were not seen after the administration of verapamil. The heart rate was consistently higher with nifedipine than during therapy with verapamil.

Discussion

Verapamil Versus Nifedipine in Chronic Stable Angina

Although several controlled clinical trials have established the effectiveness of verapamil and nifedipine in the management of patients with stable and unstable angina pectoris,[9–13] few trials have compared the effectiveness of the two drugs. Dawson et al.[14] recently compared nifedipine and verapamil in 16 patients with effort-related angina who entered a double-blind randomized trial using the same doses as those employed in the present report. Both drugs produced a similar decrease in the frequency of anginal attacks and the number of nitroglycerin tablets consumed, and a similar increase in exercise duration; however, side effects were significantly more common with nifedipine. Thus, these investigators concluded that verapamil appeared to be the calcium antagonist agent of choice in patients with chronic stable angina pectoris.[14] The ablity of this trial to detect significant differences in *effectiveness* between verapamil and nifedipine was limited by the small number of patients evaluated and by the lack of ambulatory electrocardiographic monitoring to detect asymptomatic episodes of ischemia.

The present study is the first placebo-controlled randomized clinical trial evaluating these two agents in patients with exertional angina using exercise testing *and* Holter monitoring. Compared with placebo, both verapamil and nifedipine increased exercise tolerance and the quantity of work performed during symptom-limited exercise, while decreasing the magnitude of S-T segment depression for a given workload. However, in the doses administered, the magnitude of improvement with verapamil (360 mg daily) was superior to that seen with nifedipine (60 mg daily) for all variables measured. Verapamil significantly reduced the number of asymptomatic episodes of ischemia, as determined by S-T segment shifts on Holter monitoring, whereas nifedipine did not. Moreover, therapy with verapamil was better tolerated than was treatment with nifedipine. Few adverse reactions were noted with verapamil; none were serious, and none required discontinuation of the drug. In contrast, 7 of the 32 patients developed side effects during nifedipine therapy serious enough to require its withdrawal; 6 of the 7 patients had worsening angina. These results are very similar to the findings of Dawson et al.[14]; the differences we observed in effectiveness between the two drugs was likely related to the larger number of patients in our trial.

Validation of the Study Design

When designing the present trial, we made every effort to ensure objectivity of data collection and interpretation. The trial was randomized, double-blind, and placebo-controlled, and used two sets of objective end points. Exercise testing was used for quantification of exercise tolerance under highly observed and controlled conditions, and ambulatory electrocardiographic monitoring was used to assess uncontrolled environmental influences as well as ischemic responses at rest. All of the data were analyzed by computer without knowledge of the drug assignment, and none of it relied

on subjective interpretation by either patients or by physicians.

Our protocol, like that of Dawson et al.,[14] compared fixed doses of verapamil and nifedipine rather than individually titrated doses of both drugs. The dose of verapamil used (360 mg daily) was chosen because we and others have found this dose to be well-tolerated and highly effective in relieving anginal symptoms for long periods.[7,15–17] Although both higher and lower doses of verapamil have been used by other investigators, lower doses (240 mg daily) have not been consistently effective,[18] and higher doses (480 mg daily) have been reported to produce greater adverse effects without producing significant additional benefits.[17] The dose of nifedipine used (60 mg daily) was chosen because our earlier study using 30 mg daily did not show significant effects at this dose compared with placebo. Furthermore, 60 mg daily was the principal dose employed in the multicenter placebo-controlled trials of nifedipine in effort-related angina pectoris recently conducted in the United States.[10] Although we and others have found 60 mg daily more effective than 30 mg daily, the higher dose also produced greater adverse effects. Although a still higher dose of nifedipine (30 mg or more per dose, 90 to 120 mg daily) might have improved exercise tolerance more than in the present trial, it is likely that such a dose would also have produced a still greater incidence of adverse reactions than we observed.

Previous Comparative Trials of Verapamil and Nifedipine

Winniford et al.[19] compared the effectiveness of safety of verapamil and nifedipine in patients with variant angina, most of whom had nonobstructive coronary artery disease. Their patients received verapamil (mean dose 450 mg daily) in a double-blind fashion but received open-label therapy with nifedipine (mean dose 71 mg daily). Given the limitations of this type of comparison, the two drugs were equally effective in abolishing symptomatic and asymptomatic episodes of ischemia. However, adverse effects were more common with nifedipine than with verapamil. None of the 27 patients in this study required a reduction in dose or discontinuation of therapy while taking verapamil, whereas 3 patients discontinued therapy and 7 patients had dose-limiting adverse effects while taking nifedipine.

Mechanisms Underlying Differences Between Verapamil and Nifedipine

In contrast to the comparable efficacy of the two drugs in patients with variant angina, we found verapamil superior to and better tolerated than nifedipine in patients with effort-related symptoms. The differences in the findings of the two studies are explicable if one recalls that the mechanisms underlying the antianginal effects of the calcium antagonists in exercise-provoked ischemia differ from those in variant angina. The benefits observed in patients with effort-related symptoms are likely mediated by the drugs' systemic vasodilator actions rather than their ability to block coronary vasospasm.[20,21] By reducing peripheral resistance, both verapamil and nifedipine decrease myocardial oxygen requirements for a given workload. Unfortunately, any drug-induced peripheral vasodilation causes sympathetically mediated reflex tachycardia which, if left unopposed, may detract from a drug's antianginal effects and provoke adverse reactions (such as palpitations, headaches, and angina) characteristic of sympathetic hyperactivity.[1,22] This reflex sympathetic activation is not affected by nifedipine but is attenuated by verapamil, both directly by its inhibitory action on the sinoatrial node and indirectly by a nonspecific antagonist effect on the adrenergic nervous system.[1,5] We would therefore expect verapamil to be more effective and better tolerated than nifedipine in patients with effort-related symptoms.

Our observations are consistent with these concepts. Whereas verapamil produced a mild slowing of the heart rate and nearly abolished the number of episodes of heart rate over 100 beats/min, nifedipine produced a mild reflex tachycardia, such that heart rates over 100 beats/min were seen significantly more often with nifedipine than with placebo. In 4 patients in the present study, this reflex tachycardia was sufficiently severe to provoke episodes of angina at rest, shortly after ingestion of a dose of nifedipine. Similar occurrences have been reported by others.[23–28] Therefore, the less marked effects of nifedipine in controlling angina may be related to the deleterious effects of drug-induced tachycardia, which may offset the otherwise beneficial effects of vasodilation. Successful and safe antianginal therapy with nifedipine, therefore, appears to require effective attenuation of drug-induced increases in heart rate by concomitant therapy with a beta-adrenergic blocking drug; supplemental beta blockade is not needed with verapamil. However, concomitant therapy with nifedipine and beta blocking agents may result in excessive hypotension and in the exacerbation of congestive heart failure[24,29–31]; hence, such therapy should be used with caution.

In conclusion, verapamil appears to be a more effective and better tolerated drug than nifedipine in the management of patients with chronic stable effort-related angina pectoris. The differences in the clinical responses seen with the 2 drugs appear to be explicable by differences in their effects on heart rate.

Clinical Relevance of Verapamil Plasma Levels in Stable Angina Pectoris

WILLIAM FRISHMAN, MD, EDWARD KIRSTEN, PhD, MICHAEL KLEIN, MD, MICHAEL PINE, MD, STACEY M. JOHNSON, MD, L. DAVID HILLIS, MD, MILTON PACKER, MD, and ROBERT KATES, PhD

Plasma levels of verapamil and norverapamil were evaluated in 77 patients who received oral verapamil for treatment of angina pectoris. There was a sixfold interpatient variation in verapamil plasma concentrations, but plasma concentrations were linearly related to doses of the drug (240 to 480 mg/day) in the same patient ($r = 0.81$). Plasma concentrations of norverapamil, the major active metabolite of verapamil, were similar to those of verapamil.

Although verapamil produced a significant improvement in exercise tolerance in most patients, the increase in exercise time was not related to plasma levels of the drug; however, most patients with improvement had plasma levels exceeding 100 ng/ml. An increase in the dose of verapamil from 320 to 480 mg daily produced a substantial (71%) increase in plasma levels of the drug but no significant increase in exercise tolerance (4%).

The average increase in the P-R interval with 480 mg of verapamil in these 77 patients was small (8%) (161 ± 18 to 174 ± 22 ms); only six patients had first-degree heart block. These minor effects on atrioventricular conduction were noted despite plasma verapamil concentrations in 76 patients that exceeded 100 ng/ml, a level that successfully converts supraventricular tachycardias after intravenous drug administration. The differences between the effects of oral and intravenous verapamil on atrioventricular conduction may be the result of stereoselective hepatic inactivation of verapamil's *l*-isomer.

Determination of plasma levels of verapamil is of limited value in the management of patients with angina pectoris, but may be useful in the identification of nonresponders with plasma levels less than 100 ng/ml who may benefit from a further increment in drug dose.

The direct application of pharmacokinetic principles to the optimization of individual dosing regimens has become an important aspect of pharmacotherapy. Verapamil is a calcium channel-blocking agent which is effective in the treatment of angina,[1] atrial arrhythmias,[2] systemic hypertension,[3] and hypertrophic cardiomyopathy.[4] Although there have been several reports on the pharmacokinetics of verapamil in both normal subjects and patients after administration of a single dose,[5-7] few studies have attempted to define therapeutic plasma levels during long-term oral administration of the drug in patients with ischemic heart disease.

Long-term therapy with verapamil is associated with an extremely wide interpatient variation in peak plasma levels. Because the gastrointestinal absorption of verapamil is rapid and complete,[5] this variation is likely due to the high first-pass hepatic metabolism of the drug.[5,6] Twelve metabolites of verapamil have been identified, most in only small amounts.[8] The only metabolite that appears to possess significant pharmacologic activity is norverapamil, which has about 20% of

the activity of the parent compound[9] and is not formed after intravenous administration of verapamil.[7] The objective of this investigation was to evaluate the interindividual differences in verapamil and norverapamil plasma levels during long-term therapy with verapamil and define a relation between plasma concentration of the drug and its antianginal effect.

Methods

Study patients: All patients were enrolled in one of several well-controlled multicenter clinical trials, sponsored by the Knoll Pharmaceutical Company, in which verapamil was compared with either placebo or propranolol.[10–13] All patients for whom plasma samples were available for analysis form the basis of the present report. No patient was excluded because of failure to respond to verapamil therapy or because of the development of adverse effects.

The patient group consisted of 77 patients (74 men and 3 women). All patients had effort-related angina pectoris with 3 to 15 anginal episodes per week and S-T segment changes of 1.0 mm or greater on treadmill exercise testing before treatment. The average (± standard deviation [SD]) number of episodes of angina at rest per week was 1.2 ± 0.6 and the average number of episodes of exertional angina per week was 7.3 ± 1.3, as recorded by each patient in a diary. The age of the patients averaged 58 ± 8 years (SD).

All cardioactive medications except sublingual nitroglycerin tablets were discontinued for 48 hours before entry into the study. Each study included a 2 week placebo-controlled period followed by a dose-titration phase, during which each patient received verapamil at doses of 240 mg/day (80 mg 3 times daily), 320 mg/day (80 mg 4 times daily), and 480 mg/day (120 mg 4 times daily or 160 mg 3 times daily) for periods of 1 week each. Exercise tolerance was measured for each patient by means of a standardized symptom-limited exercise test (using the Bruce protocol) at the end of the placebo period as well as at the end of 1 or more of the 3 verapamil treatment periods. In one study of 20 patients,[11] peak plasma verapamil concentrations were measured while patients were receiving 240 mg/day, 320 mg/day, and 480 mg/day, and exercise tolerance was measured at the 2 largest doses of verapamil.

Plasma verapamil determinations: Blood samples for plasma levels of verapamil and its N-demethylated metabolite (norverapamil) were drawn 1.5 to 2.5 hours after the last dose of verapamil; previous studies indicated that peak levels of both compounds occurred at this time.[7] Plasma levels of verapamil and norverapamil were quantitated by high pressure liquid chromatography at Bio-Science Laboratories, Bellwood, Illinois.[14] The assay utilized has been shown to be linear for plasma verapamil concentrations between 10 and 1,000 ng/ml.

Statistical analysis: Data are expressed as mean values ± SD. Differences from baseline were analyzed using analysis of variance procedures. Regression analysis was employed using a linear least squares fit of the data points.

Results

Interpatient variation in plasma levels: There was little relation between the dose of verapamil and plasma levels of the drug in the 77 patients in the present study; with 480 mg daily of verapamil, plasma drug levels showed a sixfold interpatient variation (Fig. 1). Four centers[10–12] administered verapamil at a dose of 120 mg every 6 hours, whereas one center[13] employed a dose of 160 mg every 8 hours. The average peak verapamil plasma level in the 56 patients who received the drug as 120 mg every 6 hours (301 ± 53 ng/ml) was similar to that in the 21 patients who were given 160 mg every 8 hours (361 ± 166 ng/ml). Five of the 77 patients had

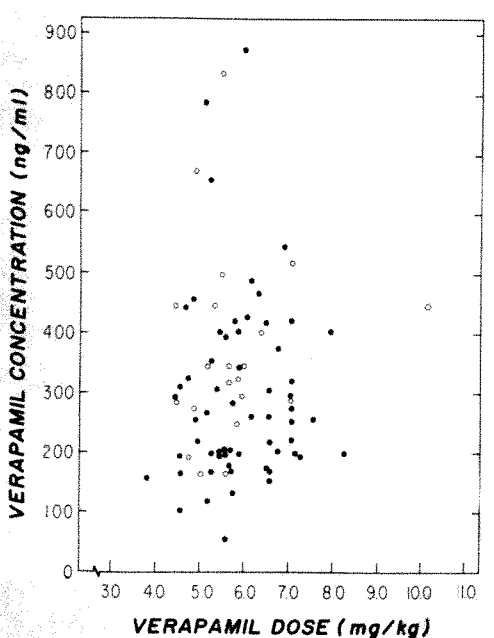

FIGURE 1. Peak verapamil concentrations versus dose in 77 patients. All patients received 480 mg of oral verapamil daily, as either 120 mg verapamil every 6 hours (**closed circles**) or 160 mg verapamil every 8 hours (**open circles**).

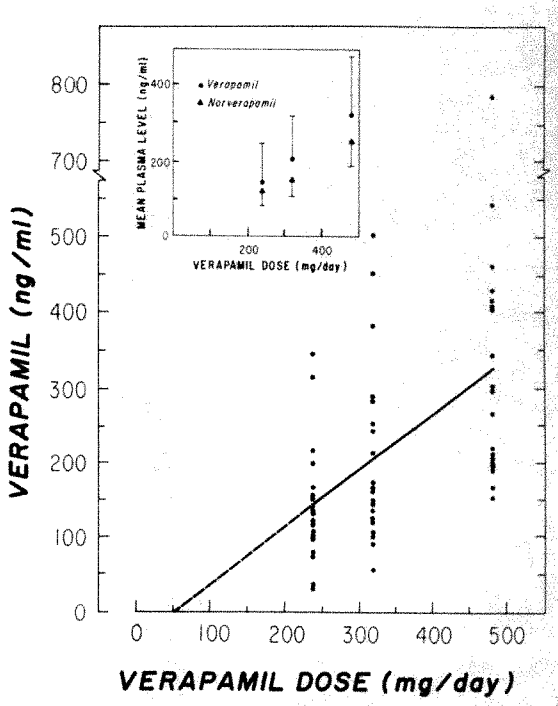

FIGURE 2. Peak verapamil concentrations after daily doses of 240, 320, and 480 mg verapamil in 20 patients. A highly significant linear relation ($r = 0.81$) was found between drug level and dose in the same patient. The **inset** depicts the mean (±SD) plasma levels of verapamil and norverapamil in these patients.

plasma verapamil levels greater than 600 ng/ml, but none exhibited adverse effects with the drug despite these very high levels.

Intrapatient variation in plasma levels: In contrast to the wide intrapatient variation, there was a close relation in the *same* patients between verapamil dose and the observed plasma levels of the drug. In a subgroup of 20 patients studied at 3 different dose levels, mean plasma concentrations of verapamil were linearly related to the dose of the drug for doses of 240 to 480 mg/day ($r = 0.81$). Mean plasma drug levels from these 20 patients were extrapolated to zero drug concentration at a dose of about 50 mg/day (Fig. 2).

Plasma levels of verapamil versus norverapamil: Plasma levels of verapamil were linearly related ($r = 0.86$) to those of its major metabolite, norverapamil, in all 77 patients who received long-term therapy with doses of oral verapamil ranging from 240 to 480 mg daily (Fig. 3). In the 20 patients who received three dose levels of the drug, steady-state plasma levels of norverapamil were approximately equal to those of the parent compound (Fig. 2 inset); the average plasma concentrations after the 240, 320, and 480 mg/day doses were 141, 206, and 323 ng/ml of verapamil and 128, 177, and 255 ng/ml of norverapamil, respectively.

Relation between plasma verapamil levels and therapeutic effects (Fig. 4): Eighteen of the 20 patients who received two different dose levels of the drug (320 mg and 480 mg daily) had complete sets of data points. Verapamil in a dose of 320 mg daily produced an overall increase in exercise duration (304 ± 85 seconds on placebo to 438 ± 108 seconds, $p < 0.05$). A greater than 20% improvement was observed in 14 of the 18 patients; all but 2 of these 14 patients had plasma verapamil levels greater than 100 ng/ml. There was no relation between the magnitude of improvement and plasma levels of the drug.

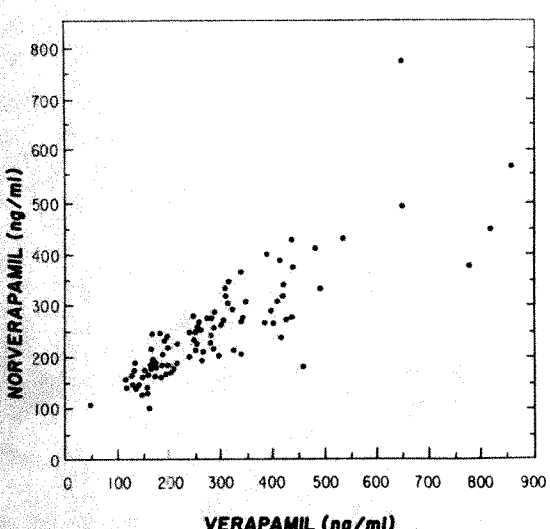

FIGURE 3. Correlation between plasma concentrations of verapamil and norverapamil in patients receiving verapamil in daily doses of 240, 320, and 480 mg.

When the dose of verapamil was increased in these 18 patients from 320 to 480 mg daily, exercise tolerance failed to improve significantly (from 438 ± 108 to 450 ± 132 seconds). Although 15 patients had a further increase in exercise tolerance, this averaged only 4% (that is, 16 seconds) despite a 71% (135 ng/ml) increase in plasma verapamil concentrations; exercise time deteriorated in 3 patients despite an increase in drug dose and a corresponding increase in circulating drug levels.

Although P-R interval prolongation was frequently seen after administration of verapamil in the 77 patients who received 480 mg daily of the drug, the average increase was only 8% (161 ± 18 to 174 ± 22 ms), although plasma verapamil concentrations exceeded 100 ng/ml in 76 patients; only six patients had first-degree heart block (P-R interval over 200 ms).

Discussion

Pharmacokinetics of verapamil: The recent development of sensitive and specific assay methods[14] has permitted delineation of the kinetic profile and metabolism of verapamil. The gastrointestinal absorption of verapamil is rapid and complete (92 to 100%)[5,7]; however, only 22% of the drug reaches the systemic circulation, largely because of its rapid metabolism in the liver during its first pass through the portal circulation.[5,7,8] Approximately 90% of verapamil is bound to plasma proteins[5]; however, this binding is not concentration-dependent over the range of 10 to 2,000 ng/ml. Verapamil protein binding is not significantly altered by renal insufficiency or cardiac catheterization, or by the addition of warfarin.[15]

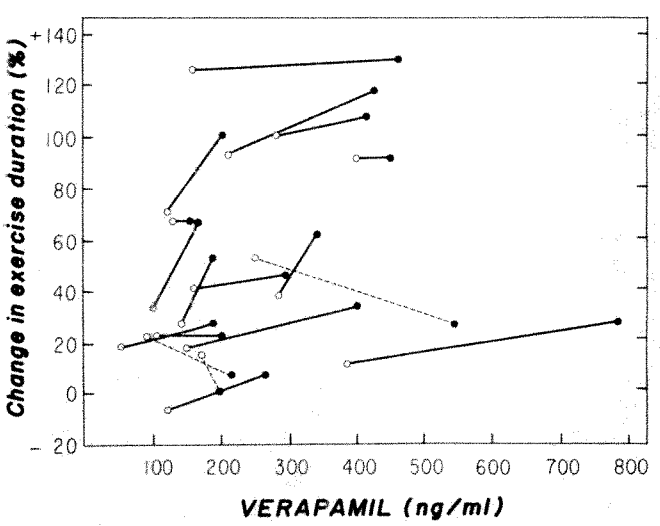

FIGURE 4. Relation between steady-state plasma levels of verapamil and its pharmacologic effects as assessed by maximal exercise tolerance testing. The percent change in exercise duration from baseline (placebo) is related to the peak verapamil plasma level measured immediately before exercise testing. Patients were tested at verapamil doses of 320 mg/day (**open circles**) or 480 mg/day (**closed circles**). Results are shown for 18 patients in whom complete data were available. Three patients (**dashed lines**) showed a decrease in exercise tolerance with increases in the dose of verapamil.

The elimination half-life is about 5 hours for verapamil and about 8 to 10 hours for norverapamil.[5,16] In a fashion similar to that for propranolol,[17] the half-life of verapamil increases with repeated oral administration of the drug because of the saturation of hepatic enzyme systems as plasma levels increase[6,16,18]; that is verapamil hepatic clearance decreases with increasing plasma drug concentrations. After 6 to 10 consecutive doses, the half-life increases to a range of 6 to 12 hours[18] without a further increase during continued administration for one year or longer.[6] In patients with liver dysfunction, the half-life of verapamil is prolonged up to 14 to 16 hours, and plasma levels of verapamil during long-term oral administration are five times those seen in patients with normal hepatic function.[19] Accordingly, the dose of verapamil should be reduced by one third to one fifth in patients with impaired hepatic function.[19,20]

Verapamil dose and plasma levels: We found that peak plasma verapamil concentrations at steady-state were linearly related to the dose of verapamil administered when drug dosage was increased in the same patients. Doubling the dose of verapamil resulted in a corresponding twofold increase in mean plasma concentrations of both verapamil and norverapamil. This linear accumulation of plasma verapamil during the administration of 240 to 480 mg/day of the drug indicates that hepatic metabolism of the drug is not characterized by a threshold response.

Plasma verapamil levels and therapeutic response: Plasma concentrations of verapamil and norverapamil varied about sixfold after 1 week's treatment with 480 mg daily, averaging 301 ng/ml in patients receiving 120 mg every 6 hours and 361 ng/ml in patients receiving 160 mg every 8 hours. These results are similar to those of Woodcock et al.,[21] who reported mean steady-state verapamil levels of 355 ng/ml with a 13-fold variation in plasma levels in patients with hypertrophic obstructive cardiomyopathy receiving 160 mg every 8 hours. The wide variation in plasma verapamil levels is likely the result of the high and variable degree of hepatic metabolic inactivation of orally administered drug. Similar interpatient variations in peak levels have been reported for the beta-adrenergic blocking agents propranolol[17] and metoprolol.[22]

Most patients who had improvement during long-term verapamil therapy had plasma levels of the drug greater than 100 ng/ml; this is similar to the plasma drug levels required for successful conversion of supraventricular tachycardia to sinus rhythm.[23] However, plasma verapamil concentrations correlated poorly with the *magnitude* of improvement in exercise duration in our patients with effort-related angina pectoris; it was not possible to predict a patient's improvement in exercise tolerance based on plasma drug levels. Anginal symptoms improved in most patients with a dose of 320 mg of verapamil daily; although some patients showed further improvement with increments in dose to 480 mg daily, such benefits were small and inconsistent, despite substantial further increases in plasma verapamil concentrations. Hence, daily doses of 320 mg of verapamil may provide near-maximal therapeutic benefit in patients with effort-related angina pectoris; other investigators have similarly suggested that the optimal dose of verapamil for angina therapy is 320 mg daily (80 mg every 6 hours)[13] or 360 mg daily (120 mg every 8 hours).[24] As with any antianginal drug, upward titration of dosage may be necessary in selected patients in order to obtain maximal benefits with verapamil.

The only drug effect reported to be significantly related to the plasma levels of verapamil is the prolongation of the electrocardiographic P-R interval; this relation has been established for both intravenous and oral drug administration.[7,25] However, in the present study, verapamil (480 mg daily) produced an increase in the P-R interval of only 13 ms (8%), even though 76 of the 77 patients achieved plasma drug levels exceeding 100 ng/ml, a level that produces effects on atrioventricular conduction sufficient to terminate most supraventricular tachycardias.[23] This rather small increase in the P-R interval during long-term oral administration might be explained by the hypothesis of Eichelbaum et al.[25] They observed that patients required plasma levels of verapamil 2 to 3 times greater during oral therapy than after intravenous drug administration in order to achieve similar effects on the P-R interval. Because the *l*-isomer of verapamil is 8 to 10 times more active than the *d*-isomer in prolonging atrioventricular conduction,[26] these investigators hypothesized that the *l*-isomer might be selectively metabolized by the liver, and hence plasma levels of the drug during oral administration might consist primarily of the less depressant *d*-isomer; in contrast, after intravenous drug administration, *d*- and *l*-isomers are present in equal concentrations. This could explain the smaller increases in the P-R interval during oral administration of verapamil than during intravenous therapy. Stereoselective hepatic inactivation has been shown to occur during long-term oral therapy with propranolol.[27]

Peak verapamil levels up to 900 ng/ml were observed in some of our patients without adverse effects; hence, delineation of a toxic level of verapamil is not possible from the data available in the present study. Toxic cardiovascular reactions (bradycardia, atrioventricular block, and hypotension) have been reported after massive doses of verapamil (2.0 to 5.6 g),[28,29] usually in setting of attempted self-poisoning in persons with normal ventricular function; recovery has usually occurred within 24 to 36 hours using only supportive measures. Plasma verapamil levels of 4,000 ng/ml were measured after the ingestion of 3.2 g of verapamil in a patient with compromised cardiac function, who recovered after the administration of intravenous calcium gluconate[30]; intravenous calcium solutions have proved effective in reversing other cases of verapamil toxicity.[31]

Contribution of norverapamil: Because it is formed by hepatic metabolism of the parent compound, norverapamil is not detected in plasma after intravenous bolus administration.[7] In our study long-term oral therapy resulted in plasma concentrations of norver-

pamil about equal to those of verapamil. Our observation that the ratio of norverapamil to verapamil remained unchanged over the therapeutic dose range of verapamil suggests that the metabolic conversion of verapamil to norverapamil is not concentration-dependent. Hence, measurement of norverapamil concentrations appears not to provide additional useful information in the management of patients with angina pectoris.

Clinical implications: Measurement of plasma drug levels may be helpful in the identification of patients who fail to respond to verapamil because of low plasma levels (less than 100 ng/ml), and hence may benefit from appropriate increases in the dose of the drug. Blood level determinations also appear important in the confirmation of iatrogenic or self-inflicted overdosage. Plasma verapamil levels cannot be used to predict the *individual* clinical responses in patients with angina pectoris.

Long-Term Effectiveness of Verapamil in Stable and Unstable Angina Pectoris

One-Year Follow-Up of Patients Treated in Placebo-Controlled Double-Blind Randomized Clinical Trials

STEPHEN SCHEIDT, MD, WILLIAM H. FRISHMAN, MD, MILTON PACKER, MD, JAWAHAR MEHTA, MD, OBERDAN PARODI, MD, and V. BALA SUBRAMANIAN, MD

The clinical responses to 12 months' treatment with verapamil were evaluated in 63 patients with stable and unstable angina pectoris in whom the effectiveness of verapamil had been established in short-term double-blind placebo-controlled randomized clinical trials.

In 41 patients with effort-related angina, long-term responses were sustained for periods exceeding 1 year. Twenty patients were evaluated by clinical history and showed a sustained reduction in frequency of anginal attacks and consumption of nitroglycerin with verapamil compared with the initial placebo control periods; the magnitude of this benefit was similar to that observed during double-blind treatment with the drug. Twenty-one patients were evaluated by serial treadmill exercise testing and showed a sustained improvement in exercise duration after 4, 8, 16, 24, and 52 weeks of verapamil treatment; withdrawal of the drug resulted in a deterioration of exercise performance to levels similar to those seen before initiation of therapy.

In 22 patients with unstable angina at rest, verapamil produced an amelioration of anginal symptoms that was sustained in most patients for longer than 1 year. However, these patients continued to have a high incidence of death and myocardial infarction in a frequency similar to that previously reported in large clinical studies using either combinations of verapamil and nitrates, nifedipine and propranolol, or propranolol and nitrates. Calcium-channel antagonists may decrease the number of patients requiring coronary artery bypass surgery for relief of refractory angina, but they do not appear to alter the natural history of the disease.

Verapamil has proved useful in the treatment of supraventricular tachyarrhythmias,[1,3] hypertrophic cardiomyopathy,[4–6] vasospastic or variant angina,[7] and chronic, stable, effort-induced angina.[8–13] Although several trials have confirmed the effectiveness of oral verapamil in patients with chronic stable angina pectoris, most trials have been of short duration, usually less than 4 to 6 weeks long. As a result, the long-term antianginal effects of verapamil and other calcium antagonists have not been well documented.

To evaluate the long-term value of verapamil in patients with ischemic heart disease, we conducted subjective and objective clinical follow-up examinations in 63 patients with stable and unstable angina pectoris, all of whom had been entered into short-term double-blind clinical trials comparing the effectiveness of verapamil with placebo or with propranolol; all were subsequently treated with verapamil for at least 1 year. Our results indicate that the beneficial effects of short-term therapy with verapamil are sustained during long-term treatment with the drug.

Long-Term Therapy of Stable Angina Pectoris

Methods

Patient population: The patient population was chosen from 66 patients with stable angina of effort who had participated in 3 randomized clinical trials. All patients had anginal pain on exertion relieved by rest or sublingual nitroglycerin, or both, occurring at least twice weekly for at least 4 weeks;

All values are means ± SEM

all patients demonstrated at least 1 mm S-T depression on two successive standardized treadmill exercise tests performed while receiving no treatment. No patient had severe hypertension or S-T segment changes while standing or during hyperventilation or during the Valsalva maneuver; none had unstable angina pectoris, acute myocardial infarction within 3 months, previous cardiac surgery, or congestive heart failure. No patient was taking digitalis, beta-adrenergic blocking drugs, long-acting nitrates, or antiarrhythmic agents before evaluation.

Trial protocol: All patients entered a randomized clinical trial comparing verapamil with either placebo or propranolol. Scheidt et al. (unpublished observations) entered 18 patients into a double-blind crossover trial comparing placebo with verapamil, given as either 320 or 480 mg daily depending on the results of an earlier single-blind dose titration phase; each drug was administered for 4 weeks. Frishman et al.[14] entered 20 patients into a double-blind crossover trial comparing verapamil (240 to 480 mg daily) with propranolol (60 to 320 mg daily); each drug was administered for 3 weeks. Bala Subramanian et al.[15] entered 28 patients into a double-blind crossover trial comparing verapamil 360 mg daily with placebo, each administered for 2 weeks.

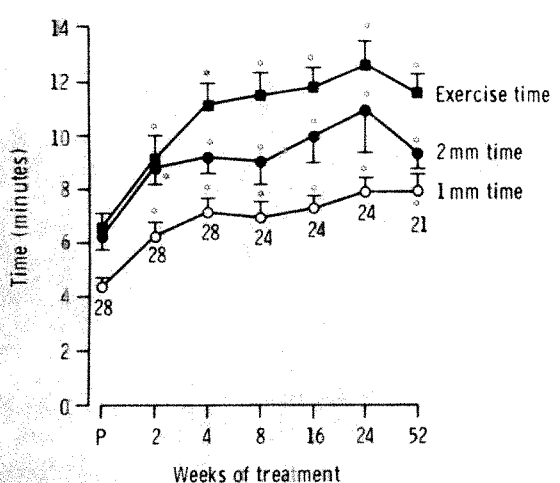

FIGURE 1. Effect of long-term treatment with verapamil on exercise time to the development of angina and to the appearance of 1 and 2 mm S-T segment depression. All values are mean values ± SEM. **Asterisks** indicate significant difference ($p < 0.001$) from placebo (P) control. The numbers under the graphs at each period indicate the number of patients studied. (Reproduced from Reference 15.)

At the end of the double-blind trial, each patient was considered for entry into a long-term verapamil follow-up protocol. Scheidt et al. entered 17 of their 18 patients into the long-term protocol; 1 patient died during the double-blind phase. Of these 17 patients, 2 failed to complete 1 year's treatment with verapamil for reasons unrelated to drug therapy: 1 because of compliance problems and 1 because of financial difficulties. Four patients received verapamil for 10 months with good results but did not complete 1 year's therapy at the time of termination of the long-term follow-up protocol. Of the 20 patients evaluated by Frishman et al., 8 patients chose to receive other therapy and 2 were considered unsuitable for long-term follow-up because of problems with compliance. The remaining 10 patients received verapamil for 12 months, but long-term data were obtained in only 9 patients; 1 patient who moved out of the state was lost to follow-up. As a result, Scheidt and Frishman followed up 20 patients on verapamil therapy for at least 1 year. There were 17 men and 3 women (age range 49 to 71 years). The doses administered (480 mg daily in 18 patients and 320 mg daily in 2 patients) were identical in each patient to those utilized during the double-blind studies.

All 28 patients evaluated by Bala Subramanian et al. were continued on long-term verapamil therapy. There were 25 men and 3 women (age range 43 to 69 years). The dose administered was 360 mg daily in each patient, identical to that utilized during the double-blind phase. All completed 4 weeks' treatment with verapamil; 4 patients were withdrawn before the 8 week evaluation because a dose of 360 mg daily of the drug could not be maintained: 1 because of first-degree heart block (0.28 second), 2 because of worsening angina (responsive to an increased dose of verapamil in 1 and to the addition of a beta-blocking drug in the other), and 1 because of an acute inferior myocardial infarction. Four patients were lost to follow-up study after 6 months of treatment; 21 patients completed 1 year's treatment with verapamil.

During the long-term follow-up period, verapamil was the only antianginal medication used. Long-acting nitrates and beta-blocking drugs were not added. Sublingual nitroglycerin was permitted during the study for relief of anginal attacks but was not used prophylactically. In addition, no patient was taking digitalis, diuretics, or antiarrhythmic agents.

Subjective and objective evaluations: All 41 patients were evaluated monthly for the first 2 months after completion of the double-blind phase, every second month until the

end of the first year, and every third month thereafter. The frequency of anginal attacks and consumption of nitroglycerin were determined from patient diaries, and heart rate and blood pressure were assessed at each return visit. Adverse effects were evaluated from a standardized questionnaire and by routine hematologic and biochemical laboratory tests.

In addition, the patients studied by Bala Subramanian et al.[15] underwent serial treadmill exercise testing after 4, 8, 16, 24, and 52 weeks of verapamil therapy. After completion of 1 year of treatment in these patients, verapamil was withdrawn; the dose was gradually reduced over 1 week and was replaced by placebo therapy for an additional 4 weeks. Treadmill testing was repeated at the end of the placebo period, and its results were compared with the exercise test during placebo treatment performed 1 year earlier. All tests were performed according to a protocol described previously[15] and were conducted 90 to 150 minutes after administration of the last dose of verapamil or placebo. Variables evaluated included the total duration of exercise and the duration of exercise until the appearance of 1 and 2 mm S-T depression.

Data analysis: The frequency of anginal attacks and nitroglycerin consumption were analyzed in the patients of Scheidt and Frishman only for the 20 patients who completed all evaluations during the entire 12 month follow-up period. Significance was determined by Wilcoxon signed rank t tests with each period compared with the baseline placebo, double-blind placebo, and double-blind verapamil phases. Exercise duration was assessed by Bala Subramanian et al. for 28 patients followed up for 4 weeks, 24 patients followed up to 6 months, and 21 patients followed up to 1 year; statistical analysis was performed by Student's paired t test. Group data are expressed as mean ± standard error of the mean (SEM).

Results

Anginal attack frequency and nitroglycerin consumption: In the 20 patients evaluated by Scheidt and Frishman, during the double-blind phases of the trial, verapamil reduced the number of anginal attacks from 19.4 ± 5.7 episodes per week on placebo to 6.9 ± 1.7 per week after 3 to 4 weeks on the drug ($p < 0.05$). During open-label verapamil therapy for 1 year, this improvement was sustained; the number of attacks throughout the follow-up period remained significantly smaller than observed during either the single- or double-blind placebo period (Table I).

During the double-blind phases of the trial, verapamil reduced the number of nitroglycerin tablets consumed from 16.2 ± 5.4 tablets per week on placebo to 7.1 ± 1.8 per week after 3 to 4 weeks of the drug ($p < 0.05$). During long-term open-label verapamil therapy, the number of nitroglycerin tablets consumed remained significantly smaller than that of either the single- or double-blind placebo period for the first 10 months (Table I). However, at 12 months nitroglycerin consumption was no longer significantly lower than the placebo baseline, but it was also not significantly higher than that observed during the first 4 months of verapamil therapy. These unusual findings at the 12 month follow-up visit are the result of enormous interindividual variation. Seventeen patients continued to have sustained responses; the number of anginal attacks and tablets of nitroglycerin consumed at 12 months remained similar to or below the mean of the preceding 6 observation periods. However, 3 patients had an increase in the frequency of anginal attacks between the 10th and 12th months of verapamil treatment (from 8.3 episodes per week on double-blind verapamil to 9.5 episodes per week during the initial 10 months' therapy and to 22.7 episodes per week at 12 months). One of these 3 patients had relief of angina after coronary artery bypass surgery; in the other 2, nifedipine was substituted for verapamil but without alteration in anginal frequency or nitroglycerin consumption.

Hemodynamic variables: In the 20 patients evaluated by Scheidt and Frishman, verapamil reduced systolic and diastolic blood pressure during double-blind therapy with the drug, and this reduction was sustained over the 12 month period in most patients. Diastolic blood pressure was more consistently reduced than was systolic pressure (Table I); diastolic pressure decreased from 83.8 ± 2.9 to 75.2 ± 2.6 mm Hg on verapamil (double-blind), and this reduction was sustained (73.7 ± 2.2 mm Hg) at 12 months. Heart rate was unchanged by verapamil therapy initially, but long-term treatment produced a progressive sustained modest decrease (from 76 to 67 beats/min) after 12 months. Two of the 3 patients who had an abrupt increase in the frequency of anginal attacks between 10 and 12 months also had an unexpected increase in blood pressure and heart rate at the time of this evaluation.

Treadmill exercise performance (Fig. 1): In the 28 patients evaluated by Bala Subramanian et al., the duration of exercise increased from 6.6 to 0.5 minutes on placebo to 9.2 ± 0.8 minutes after 2 weeks and to 11.4 ± 0.8 minutes after 4 weeks of verapamil therapy. This improvement was maintained during the 1 year follow-up period: 11.6, 11.8, 12.8, and 11.7 minutes after 8, 16, 24, and 52 weeks, respectively. The duration of exercise until the appearance of 1 and 2 mm S-T depression was prolonged after 2 weeks' treatment with verapamil, and this was sustained at repeat evaluation after 4 to 52 weeks.

All 28 patients had angina during the placebo period, but angina limited exercise in only 13 of the 28 verapamil-treated patients after 2 weeks and in only 8 of 24 treated patients after 4 weeks. No patient who became angina-free at 4 weeks had angina at 8, 16, 24, or 52 weeks of long-term verapamil therapy.

Seventeen of the 21 patients completing 1 year's treatment with verapamil agreed to have the drug withdrawn in order to assess its continued efficacy. Six of these 17 patients could not undergo repeat exercise testing; 3 had angina at rest, 1 had a marked increase in the frequency of anginal attacks, and 2 could not tolerate the recurrence of effort-related angina after 1 year. The mean exercise time in the 11 patients who underwent repeat treadmill evaluation was 6.9 ± 0.8 minutes, which was not significantly different from the values obtained in these patients during placebo therapy 1 year earlier (6.7 ± 0.5 minutes).

Adverse reactions: Of the 48 patients followed on verapamil for longer than 4 weeks, constipation was the most commonly noted adverse reaction, occurring in one third to one half of the patients evaluated. This was controlled by dietary adjustment or by laxatives in most

patients and resolved despite unchanged doses of verapamil and without any intervention in the others. Four patients had leg edema (bilateral in 2 and unilateral in 1) without signs of heart failure; edema was controlled by intermittent small doses of diuretic agents in all cases.

Seven patients exhibited cardiac rhythm disturbances. Two patients had junctional rhythms, accompanied by slight dizziness in 1 of them. Two patients had asymptomatic sinus bradycardia. One patient had atrial fibrillation with a slow ventricular response accompanied by mild dizziness; 2 patients had asymptomatic first-degree heart block. All symptoms and conduction disturbances disappeared when the dose of verapamil was reduced without a loss of antianginal efficacy.

One patient had acute urinary retention requiring bladder catheterization and subsequent transurethral prostatectomy; after surgery, he continued on verapamil therapy without further problems. Two patients reported occasional urinary frequency, which disappeared without dose adjustment. No significant hematologic or biochemical abnormalities were noted.

Verapamil therapy was not discontinued in any patient because of the development of adverse reactions.

Long-Term Therapy of Unstable Angina Pectoris

Methods

Patient population: The patient population consisted of 27 patients with unstable angina at rest who had participated in two randomized clinical trials. All patients had anginal pain at rest associated with electrocardiographic S-T segment elevation, depression, or both. Parodi et al.[16] evaluated 12 patients, aged 34 to 70 years; 7 had both exertional and rest angina, whereas the remaining 5 had only rest angina with preserved exercise tolerance. Obstructive coronary artery disease was confirmed in 8 of the 9 patients who underwent coronary arteriography. Mehta et al.[17,18] evaluated 15 patients, aged 42 to 80 years; 13 patients had both exertional and rest angina, whereas the remaining 2 had only angina at rest. All 12 patients who had coronary arteriography had significant obstructive coronary artery disease. No patient was taking beta-adrenergic blocking drugs during the period of evaluation.

Trial protocol: All patients entered a randomized clinical trial comparing verapamil with placebo. The study protocol of Parodi et al. consisted of a 2 day run-in period followed by four 2 day treatment periods alternating verapamil (480 mg daily) and placebo. The protocol of Mehta et al. employed a 24 hour placebo run-in period followed by randomization to either placebo or verapamil (320 mg daily); individual responses were determined at the end of each 24 hour period, with responders continuing on their effective regimen and nonresponders advancing from placebo to low-dose verapamil (320 mg daily) and from low-dose to high-dose verapamil (480 mg daily).

At the end of the double-blind trial, all patients were considered for long-term therapy with verapamil. All 12 patients evaluated by Parodi et al. were begun on long-term treatment, but only 10 patients were followed for a mean of 47 weeks; 2 were lost to follow-up. Only 12 of the 15 patients evaluated by Mehta et al. were started on long-term verapamil therapy: 1 had had a myocardial infarction during the double-blind trial, and 1 had failed to respond to verapamil therapy. Follow-up data are available for at least 12 months in all 12 patients and for up to 21 months in 6 patients.

During the long-term 1 year follow-up period, verapamil therapy was administered in doses identical to those found effective during the double-blind phase of the trial; these doses were altered only if patients had increasing angina (1 patient in whom the dose was increased from 480 to 640 mg daily) or notable side effects (constipation in 2 patients in whom the dose was decreased from 320 to 240 mg daily). Long-acting nitrates were utilized in 15 patients, but the doses utilized were similar to those administered in each patient before treatment with verapamil and remained unchanged during the period of follow-up. Concomitant therapy with beta-adrenergic blocking drugs was not employed. Sublingual nitroglycerin was permitted during the study for relief of anginal attacks but was not used prophylactically.

Long-term evaluation: All patients were evaluated periodically in terms of symptomatic status, specifically frequency of anginal attacks and number of nitroglycerin tablets consumed per week. Medical therapy was considered to have failed if patients had a myocardial infarction or angina unresponsive to increasing doses of verapamil, or died suddenly. Adverse effects of verapamil therapy were assessed at each clinical evaluation.

Results

Short- and long-term clinical results: In the 12 patients evaluated by Parodi et al.,[16] verapamil markedly reduced the number of symptomatic and asymptomatic episodes of S-T segment depression compared with placebo treatment. After completion of the short-term trial, 1 patient had a myocardial infarction while in the hospital, 8 were discharged from the hospital free of symptoms, and 3 others had occasional (1 to 3 episodes/week) attacks of angina on effort. Of the 10 patients who were followed up on long-term verapamil therapy, 7 remained free of pain and 3 continued to show a reduction in the number of ischemic episodes (averaging 2 per week).

Twelve of the 15 patients treated by Mehta et al.[17] had at least a 50% reduction in anginal attacks during short-term verapamil therapy, but these patients subsequently had a highly variable course.[18] Two of the 12 patients died within 1 week of discharge from the hospital, 1 with a myocardial infarction and another with sudden death. A third patient had an inferior wall myocardial infarction 2 weeks after discharge. Anginal frequency increased in 1 patient 1 month into follow-up despite increasing doses of verapamil (up to 640 mg daily), and therapy with the drug was discontinued. One patient was found to have left main coronary artery disease 6 months after discharge and underwent coronary artery bypass surgery, although he remained asymptomatic on verapamil. In general, symptomatic responses to verapamil were excellent, and the magnitude of effect seen after 1 week of therapy was maintained in most patients for the 12 month follow-up period (Fig. 2).

Seven patients were followed up by Mehta et al. for more than 1 year (up to 21 months). One patient had an

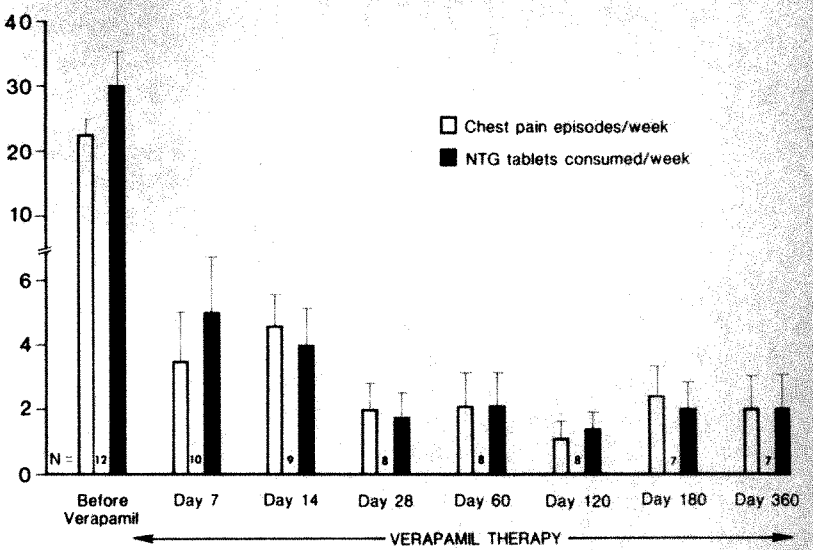

FIGURE 2. Weekly frequency (± SEM) of anginal episodes and nitroglycerin (NTG) consumption in 12 patients treated with verapamil on an ambulatory outpatient basis for 12 months. All 12 patients had responded to verapamil during the initial hospitalization. At the end of 12 months, 7 patients were still taking verapamil with good clinical responses.

uncomplicated inferior wall myocardial infarction at the end of 12 months' therapy with verapamil. The other 6 patients, however, continued to exhibit excellent symptomatic responses to verapamil therapy. Mean chest pain frequency in these 6 patients after 21 months' follow-up was 1.0 ± 0.6 episodes per week, and mean nitroglycerin consumption was 1.1 ± 0.5 tablets per week.

Adverse effects: Adverse reactions during long-term verapamil therapy were not reported in the patients treated by Parodi et al. Of the 12 patients followed up by Mehta et al., 7 had constipation, which was mild in 6 cases. P-R interval prolongation was observed in 4 patients, but only 1 of these had first-degree heart block, which was asymptomatic. The cardiothoracic ratio in all 12 patients remained unchanged during long-term verapamil therapy (47 ± 2% before and 46 ± 2% after verapamil). In 1 patient who failed to respond to verapamil, facial erythema developed at a dose of 640 mg daily; upon discontinuation of the drug, the erythema disappeared over 2 weeks.

Discussion

Verapamil is a calcium channel blocking agent which has been used for the treatment of stable and unstable angina pectoris for over a decade. Initial studies failed to demonstrate its efficacy in chronic stable angina,[8] but this was likely related to the small doses of verapamil administered (240 mg daily or less). Subsequent placebo-controlled double-blind studies using 320 to 480 mg daily demonstrated the short-term effectiveness of verapamil in stable angina pectoris for 4 to 8 weeks[9–13] and in unstable angina pectoris for 48 to 96 hours,[16,17] but few investigations have been conducted to show that these short-term benefits are sustained during long periods of drug administration.

The present report attempts to provide information concerning the long-term usefulness of verapamil therapy by reporting the follow-up results in patients who entered randomized clinical trials. Although such long-term data are not placebo-controlled, documentation of drug efficacy was confirmed initially by comparison with placebo-treated periods; therefore, maintenance of improvement during long-term verapamil treatment at levels similar to those achieved with verapamil during double-blind therapy can more confidently be attributed to the beneficial effects of the drug than if such long-term evaluations had not been preceded by a placebo-controlled drug response.

Long-term effectiveness in chronic stable angina: In patients with effort-related angina, verapamil reduced anginal attack frequency and nitroglycerin consumption when compared with treatment with placebo, and the magnitude of improvement seen during short-term treatment was sustained in most patients during long-term verapamil therapy. Only 3 of 41 patients followed up for at least 1 year exhibited an increase in anginal frequency on therapy, and these clinical exacerbations also failed to respond to therapy with alternative calcium channel blocking drugs. This sustained improvement was confirmed by standardized exercise testing; the prolongation of exercise time seen during short-term therapy was maintained after 1 year of verapamil treatment, and these benefits disappeared rapidly when the drug was withdrawn. The duration of exercise after withdrawal of verapamil for 1 year was similar to that seen during exercise testing before institution of the drug; this observation indicates that the sustained benefits of verapamil therapy were the result of drug treatment and were not due to an alteration in the national history of the disease.

Long-term effectiveness in unstable angina: Although a number of therapeutic modalities have been proposed for the treatment of patients with unstable angina associated with obstructive coronary artery disease, any short-term therapy may appear worthwhile

if placebo controls are not used, since many patients with unstable angina have a spontaneous remission of symptoms.[19] On other hand, uncontrolled observations during long-term therapy often prove inconclusive since the ambulatory course of the disease varies from the in-hospital course, and a large number of patients continue to have ischemic episodes despite optimal medical therapy and often require coronary bypass surgery for relief of symptoms; myocardial infarction and sudden death also occur with a variable frequency.[20] In the 22 patients followed up long-term in the present study, verapamil proved effective compared with placebo in the short-term relief of symptoms in each patient. Although this clinical improvement was generally well maintained, myocardial infarction and sudden death continued to occur; coronary artery bypass surgery, however, was not performed for relief of symptoms in any patient.

These results are similar to the more extensive but uncontrolled observations of Severi et al.,[21] who treated 120 patients with angina at rest accompanied by S-T segment elevation with verapamil and nitrates for 2 to 8 years. The improvement in anginal symptoms observed in most patients was sustained during the follow-up period; only 12% of patients had an exacerbation of anginal symptoms during long-term verapamil therapy, and 50% of patients became completely pain-free by the fourth year of follow-up. Despite these symptomatic benefits, however, these patients had a high incidence of myocardial infarction and death (22% and 5%, respectively, within 1 year). These results are remarkably similar to those obtained in a double-blind trial reported by Gerstenblith et al.,[22] who found that nifedipine reduced the number of patients who required coronary artery bypass surgery for relief of anginal symptoms, but failed to alter the number of patients who had myocardial infarction or died (16 and 7%, respectively, within 4 months); furthermore, benefits were limited to those patients with S-T segment elevation during episodes of pain. The incidence of myocardial infarction and death in the series of Severi et al. and the study by Gerstenblith et al. are similar to those described in the National Cooperative Study Group comparison of medical (propranolol and nitrates) and surgical therapy.[20] However, in contrast to the experience with calcium antagonists, a large proportion (40%) of patients treated with propranolol and nitrates subsequently had severe angina poorly responsive to medical therapy. Therefore, calcium antagonists appear to reduce the number of patients who require bypass surgery for relief of angina but do not appear to alter the the frequency of myocardial infarction and death.

Safety of long-term verapamil therapy: Verapamil was very well tolerated in the 63 patients we followed up for longer than 1 year. The most common adverse reaction was constipation; this was usually readily responsive to change in diet or mild laxatives. Conduction system disturbances were occasionally seen, but these were usually asymptomatic and responded to a reduction in the dose of verapamil. The peripheral edema noted in a few patients was relieved by the intermittent use of diuretics.

We did not observe potentially serious adverse reactions of verapamil therapy (hypotension, congestive heart failure, or hepatotoxicity) in any of our patients, even though rare instances have been reported by other investigators.[23–25] The incidence of these reactions appears very low and should not deter clinicians from using verapamil as a safe and effective long-term antianginal drug.

Comparative Effects of Abrupt Withdrawal of Propranolol and Verapamil in Angina Pectoris

WILLIAM H. FRISHMAN, MD, NEAL KLEIN, MD, JOEL STROM, MD, MARTIN N. COHEN, MD, HARRY SHAMOON, MD, HOWARD WILLENS, MD, PHILIP KLEIN, MD, STEVEN ROTH, MD, LOUIS IORIO, MD, THIERRY LeJEMTEL, MD, SIMCHA POLLACK, PhD, and EDMUND H. SONNENBLICK, MD

The potential hazards of abrupt withdrawal of propranolol have been described in patients with angina pectoris; however, the effects of abrupt withdrawal from long-term therapy with verapamil have not previously been investigated. The comparative effects of withdrawal from long-term treatment with propranolol and verapamil were assessed in a placebo-controlled double-blind randomized crossover study of 20 patients with stable angina pectoris. Patients received placebo for 2 weeks, then increasing doses of propranolol (60 to 320 mg/day) or verapamil (240 to 480 mg/day) for 3 weeks. Patients were then abruptly withdrawn from drug onto placebo for 1 week, followed by crossover to the other drug treatment and a second withdrawal period.

All 20 patients were withdrawn from verapamil without evidence of a rebound increase in frequency of anginal attacks, blood pressure, heart rate, or rate-pressure product and without a rebound deterioration in exercise tolerance. In contrast, with propranolol withdrawal, 2 patients (with the highest baseline angina attack rate) had a severe exacerbation of their anginal syndrome and could not undergo formal exercise testing; the other 18 patients were withdrawn from propranolol without incident. Plasma catecholamines were increased during exercise compared with rest during all treatments; however, the levels of catecholamines during exercise were significantly higher with propranolol than with verapamil and placebo ($p < 0.05$). Levels of exercise catecholamines returned to placebo baseline values after withdrawal of propranolol.

Increased severity of angina pectoris, supraventricular and ventricular arrhythmias, myocardial infarction, and sudden death have been reported in patients with ischemic heart disease who are abruptly withdrawn from long-term oral therapy with propranolol.[1-4] Little information is available concerning the exact frequency and mechanism of these propranolol withdrawal phenomena, although the possibility of sympathetic hypersensitivity has received the most interest.[5,6] Other explanations include progression of underlying coronary artery disease,[3] enhanced platelet aggregation,[7] increased triiodothyronine levels,[8] alterations in plasma renin activity,[3] or continued high levels of physical activity despite withdrawal of propranolol.[3]

Calcium-channel antagonists are now considered important modalities in the management of patients with ischemic heart disease[9] and supraventricular arrhythmia.[10] However, despite their increasing clinical use, little is known regarding the effects of abrupt treatment withdrawal from these medications.

We recently reported the results of a placebo-controlled double-blind randomized crossover trial that compared the antianginal effectiveness of long-term oral therapy with propranolol and verapamil in patients with angina pectoris.[11] Using data obtained from this same trial, we now report on the comparative effects of abrupt withdrawal from long-term treatment with verapamil and propranolol.

Methods

Subjects: The study group consisted of 20 ambulatory patients (19 men and 1 woman) whose characteristics were described in our original report.[11] Each patient had a primary diagnosis of chronic stable angina for at least 3 months before enrollment. At least 3 attacks of angina per week were required for entry; each patient also demonstrated an abnormal response on 2 occasions to a multistage treadmill exercise test with at least 1 mm of flat or downward-sloping S-T segment depression 0.08 second after the J point. All patients signed an informed consent form approved by the Committee on Clinical Investigations of the Albert Einstein College of

From the Divisions of Cardiology and Endocrinology, Department of Medicine, Albert Einstein College of Medicine, Bronx, New York. This study was supported in part by Grant HL 00653-2 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland.

Medicine. Patients were excluded on the basis of criteria that we previously described.[11]

Study design: The study protocol followed a placebo-controlled double-blind randomized crossover design.[11] Briefly, it consisted of an initial 2-week single-blind placebo run-in phase, during which time each patient received a placebo verapamil tablet (identical to an 80 mg tablet) and a placebo propranolol capsule (identical to an opaque gelatin capsule used throughout the study) every 8 hours. Thereafter, each patient received increasing doses of verapamil (240 mg/day, 80 mg every 8 hours; 320 mg/day, 80 mg every 6 hours; and 480 mg/day, 120 mg every 6 hours) or propranolol (60 mg/day, 20 mg every 8 hours; 160 mg/day, 40 mg every 6 hours; and 320 mg/day, 80 mg every 6 hours) over a 3 week titration period. After the initial dose titration, the patients underwent a 3 day down-titration phase, during which the amount of medication was decreased approximately 33% per day. The patients then entered a 5 to 7 day placebo period. After completion of this second placebo period, each patient crossed over to the other medication regimen, and the dose-titration, down-titration, and placebo phases were repeated.

Methods of observation: The patients were seen every week after entering the first-dose titration period. Daily diaries were reviewed and consumption of nitroglycerin tablets and study medications was assessed. Supine and standing heart rate and blood pressure were measured at each visit. Exercise tests were performed and blood levels of propranolol, verapamil, and norverapamil[12,13] were determined during the placebo period, during each dose-titration stage, and after withdrawal.

Exercise protocol: The exercise protocol followed that described by Bruce.[11,14] Each test was analyzed for heart rate, systolic blood pressure, rate-pressure product, and S-T segment displacement achieved at maximal effort, as well as total exercise duration. Exercise work was calculated as previously described.[11]

Plasma catecholamine levels: Blood samples for plasma catecholamine levels were obtained in a subgroup of 10 patients during rest in the supine and standing positions and at the end point of maximal upright treadmill exercise. Determinations were made during placebo baseline, on maximal propranolol and verapamil therapy, and 1 week after treatment withdrawals. Samples of blood were obtained from an indwelling venous catheter with a minimum of patient stimulation and collected in chilled tubes containing ethyleneglycol-bis(beta-amino-ethyl ether) N,N′-tetraacetic acid (EGTA) and reduced glutathione. The samples were immediately spun, and the plasma was separated and frozen at −20° C. The samples were coded and the plasma epinephrine and norepinephrine levels measured with use of a single isotope-derivative technique.[15]

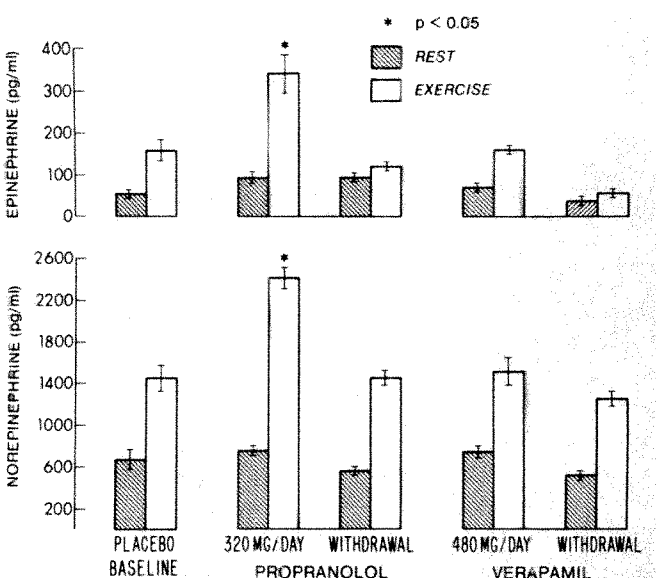

FIGURE 1. The effects of placebo, high-dose propranolol, high-dose verapamil, and their treatment withdrawal on plasma epinephrine and norepinephrine levels obtained at rest (standing) and at maximal exercise (standing). The increase in plasma catecholamines from rest to exercise is significant during all treatment periods. **Asterisks** indicate a significant difference between values on active drug therapy compared with values during administration of placebo.

Statistical analysis: All results are reported as means ±1 standard deviation except in Figure 1, where the standard

error of the mean is used as the index of dispersion. In comparing the effects of each drug and treatment withdrawal with placebo baseline, a modified Fisher least significant difference test was employed after one-way analysis of variance yielded a significant result. Differences were considered significant if the p value was less than 0.05.

Results

Patients: All 20 patients who entered the study were successfully titrated to doses of 320 mg/day of propranolol and 480 mg/day of verapamil. Drug compliance (determined by medication counts) for the placebo baseline, two-drug treatment, and two withdrawal phases (placebo) was 98 ± 10%. Plasma drug levels confirmed patient compliance, since a linear relation between dose and plasma level was observed. One week after active therapy was withdrawn, there was no trace of either drug in the blood.

All 20 patients were withdrawn from long-term therapy with verapamil and underwent exercise without evidence of deterioration from placebo baseline status. Eighteen patients were withdrawn from propranolol without difficulty; however, the 2 remaining patients who had the most severe angina at the start of the study, exhibited ischemic changes at rest on the electrocardiogram one week after therapy with propranolol was withdrawn, and could not undergo formal exercise testing during the final visit of the study. No patient in either treatment group had an acute infarction during the withdrawal periods.

Effects on resting and exercise blood pressure and heart rate (Tables I and II): Compared with the placebo baseline, both verapamil and propranolol therapy lowered the standing heart rate at rest and decreased systolic pressure, heart rate, and the rate-pressure product during exercise. After withdrawal of both verapamil and propranolol, there was a return of mean resting heart rate and exercise-induced changes in heart rate, blood pressure, and rate-pressure product toward baseline values without evidence of rebound hemodynamic changes. Hemodynamic variables after abrupt withdrawal of verapamil were similar to their placebo baseline values; after withdrawal of propranolol, supine systolic and diastolic blood pressures were lower than their values during placebo therapy ($p < 0.01$).

Effects on angina pectoris and nitroglycerin consumption (Table II): Subjectively, all 20 patients experienced relief of symptoms with both propranolol and verapamil compared with placebo. After the withdrawal of verapamil, the frequency of anginal attacks returned toward their placebo values without evidence of rebound effects. After withdrawal of propranolol, there was a slight but insignificant increase in anginal attacks and nitroglycerin consumption from placebo baseline values. However, 2 patients exhibited ischemia at rest after withdrawal of propranolol; no patient did after withdrawal of verapamil.

Effects on exercise tolerance and work, and the exercise electrocardiogram (Table II): Compared with placebo, both propranolol and verapamil increased the duration of treadmill exercise time and work ($p < 0.01$). After withdrawal of both verapamil and propranolol treatment, there was a return of exercise tolerance toward baseline. During placebo therapy, 4 of the 20 patients had ventricular ectopy at peak exercise, which was reduced by both propranolol and verapamil, but returned without exacerbation after each treatment withdrawal.

Effects on plasma catecholamines (Fig. 1): With exercise, there was a significant increase in both plasma epinephrine and norepinephrine levels compared with resting values ($p < 0.01$). Compared with placebo, there was no difference in the effect of verapamil on plasma catecholamine levels recorded at rest and exercise. With propranolol, there was no change in resting plasma catecholamine levels; however, during exercise there was a significant increase in plasma epinephrine and nor-

epinephrine determinations compared with exercise levels during treatment with placebo and verapamil ($p < 0.05$). After withdrawal of verapamil and propranolol, rest and exercise catecholamine levels returned to placebo baseline values.

Discussion

Many cardiovascular drugs used to alter left ventricular preload and afterload, or the function of the sympathetic nervous system activate compensatory physiologic mechanisms, and the abrupt withdrawal of some of these drugs has been reported to cause adverse rebound withdrawal phenomena.[16–18] Abrupt withdrawal of propranolol, clonidine, and nitroprusside can produce deleterious rebound effects that suggest excessive sympathetic activity.[1–3,19,20] However, other cardiovascular drugs cause both reflex and end-organ receptor readjustments, and yet do not produce rebound phenomena when therapy is abruptly withdrawn.[21,22] The effects of abrupt withrawal from long-term therapy with calcium-channel blocking agents have not previously been elucidated.

Propranolol withdrawal: With propranolol, a nonselective beta-adrenergic blocking agent, withdrawal effects in patients with coronary artery disease include accelerated angina pectoris, myocardial infarction, ventricular arrhythmias, and sudden death.[1,2] Only a small percentage of patients with coronary artery disease and stable angina pectoris will experience problems after sudden cessation of propranolol therapy[3]; this effect appears most marked in patients in whom propranolol is withdrawn before open-heart surgical procedures.[23] Usually, the patients with angina pectoris who exhibit the greatest benefit from propranolol are those most likely to exhibit symptomatic rebound reactions when the drug is withdrawn.[1–3]

Long-term therapy with propranolol has been shown to increase the number of beta-adrenergic receptors in animals and human volunteers[18]; hence, it has been hypothesized that withdrawal symptoms are secondary to the residual increase in the number of beta-adrenergic receptors that occurs when propranolol is no longer present in the body.[3,16] Hypersensitivity to adrenergic stimulation after propranolol withdrawal has been demonstrated in normal and hypertensive human subjects.[5,6,24] This sensitivity to exogenous catecholamines appears to be greatest by the sixth day after abrupt withdrawal of propranolol, at a time when the drug has disappeared from the plasma.[6]

In our double-blind study, all 20 patients were withdrawn from long-term therapy with propranolol, 320 mg/day, placed on placebo, and evaluated 7 days later. Although there were no myocardial infarctions, 2 patients with the most severe angina at study entry experienced rebound phenomena on propranolol withdrawal and could not undergo exercise testing because of resting electrocardiographic abnormalities; these 2 patients did not have this reaction after verapamil withdrawal. The remaining 18 patients were withdrawn from propranolol and verapamil without a deterioration from the placebo baseline status. However, we found little evidence of an adrenergic hypersensitivity phenomenon in any patient after treatment withdrawal. Plasma catecholamines, which were elevated during exercise with propranolol therapy, returned to placebo baseline levels 1 week after withdrawal; heart rate and blood pressure, at rest and during exercise, returned toward placebo baseline values without evidence of rebound hemodynamic changes. Our findings are in agreement with those of other investigators who found only a small percentage of patients manifesting problems after abrupt cessation of propranolol therapy.[1,2] The lack of greater withdrawal effects with propranolol in this study might reflect a withdrawal period that was too short, a prolonged action of the drug despite its short plasma half-life,[25] the actions of active metabolites,[25] or a training effect.

Verapamil withdrawal: The cardiovascular effects that follow abrupt withdrawal a long-term therapy with calcium-channel antagonists have not been systematically investigated. There have been only rare individual case reports describing rebound phenomena in patients abruptly withdrawn from long-term verapamil therapy.[26] However, rebound phenomena were not observed when patients with vasospastic angina,[27] unstable angina,[28] and systemic hypertension[29] were withdrawn from verapamil and given placebo as part of the protocol of controlled clinical trials. In contrast, rebound phenomena are frequently observed when propranolol is abruptly discontinued during the performance of placebo-controlled trials.[2] In the present double-blind controlled study, all 20 patients with stable angina pectoris were withdrawn from long-term therapy with verapamil, 480 mg/day, and given placebo without an exacerbation of angina pectoris in any patient. After verapamil withdrawal, there was a return of anginal symptoms, exercise performance, and hemodynamic responses toward placebo baseline values with no evidence of rebound events. The lack of withdrawal effects with verapamil might, however, reflect a withdrawal period that was too short, a prolonged action of the drug despite its short plasma half-life,[30] the actions of active metabolites,[30] or a training effect.

An interesting finding in this study was the absence of any effect on plasma catecholamine levels at rest and during exercise with verapamil treatment. Vasodilator therapy in hypertension is usually associated with an activation of the sympathetic nervous system in response to the decrease in systemic resistance.[31] In this study, verapamil caused less sympathetic discharge for similar levels of exercise than did propranolol. No differences were observed in the effects of placebo, verapamil, and verapamil withdrawal on levels of plasma norepinephrine and epinephrine measured at rest and during exercise. This atypical sympathetic response to vasodilator therapy may be the result of verapamil's actions on the slow calcium channel; calcium may be important in the release of catecholamines from the adrenal medulla, and verapamil may inhibit this release.[32–34] Accordingly, the antianginal and antiarrhythmic effects of verapamil may be mediated in part by an inhibition or reduced rate of catecholamine re-

lease in human beings. It appears that although propranolol blocks beta-adrenergic stimulation by catecholamines at the receptor level, verapamil may reduce the catecholamine response to exercise.

Clinical implications: Problems with abrupt withdrawal of long-term therapy with propranolol in patients with angina pectoris (not undergoing surgery) are uncommon and appear unrelated to heightened adrenergic activity. Caution should still be exercised when attempting to withdraw patients with angina from this treatment procedure, especially before surgery. There appear to be no adverse reactions after withdrawal of long-term verapamil treatment; however, further investigations need to be done to confirm these early observations.

Acknowledgment

We express our sincere appreciation to Susan Kreitzer for her major technical contributions and to Mary Senatore and Mary Jo Soreca for their valuable help in preparing the manuscript. We also thank Knoll Pharmaceutical Company, Whippany, New Jersey, for supplying verapamil.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as Methods, Results, and Comments. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

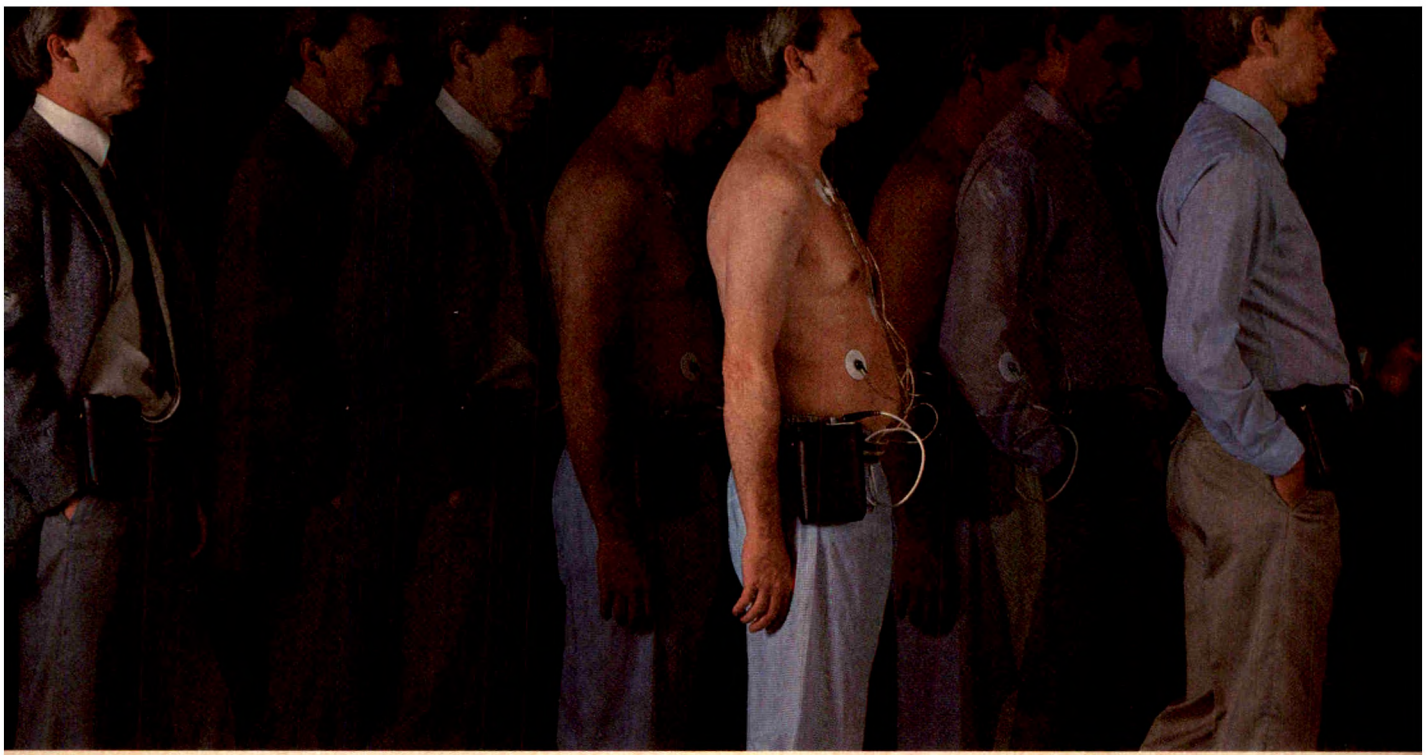
REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

> **Journal:** Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.
>
> **Chapter in Book:** Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.
>
> **Book:** Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.



Q-SCAN TELLS ALL.

Now you can look at every single heartbeat of your patient's day—without wading through complicated charts or relying on mechanical analysis. Because now there's Q-Scan, a new full-disclosure Holter monitoring system from Quinton.

The information you need in a simple-to-read format.

Q-Scan was designed to make the best use of both your time and expertise. It doesn't make value judgments. Instead it gives you *all* the information you need to make your diagnostic decisions.

In just six minutes, it accurately reproduces every heartbeat from a 24-hour period in a simple-to-read report. You can print the entire 24 hours. Or just those segments that interest you.

Q-Scan gives you a choice of paper, too. A high-speed ultraviolet printer is standard, with a hard copy printer available as an option. An innovation in Holter monitoring, the hard copy printer gives you permanent black and white copies on inexpensive paper.

Magnification of key data segments.

With Q-Scan, you have the option of taking a closer look at critical time periods. Simply choose the time you'd like to examine. Q-Scan will automatically expand and print those segments. Or, you can evaluate the trace full-size on standard ECG paper, using the optional chart recorder.

For your convenience, Q-Scan also has an optional Arrythmia Detection Program. It gives you an hour by hour summary of abnormal beats and average heart-rate in a simple-to-read report. Abnormal beats are counted and classified in premature and wide, premature and narrow, and couplet, run and non-classified categories.

INTRODUCING THE HOLTER SYSTEM THAT NEVER MISSES A BEAT.

Hospital proficiency. Office economy.

With Q-Scan, you can generate top quality diagnostic information right in your office—without special staffing or training. Q-Scan is simple to use. And priced to be affordable for almost any practice. With a lower cost per test than outside services.

Most important, Q-Scan is manufactured with the same quality and dependability that's made Quinton the leader in cardiac electronics.

For information on Q-Scan or Quinton's Q family of products, call or write Quinton Instrument Company, Cardio Fitness Division, 2121 Terry Avenue, Seattle, Washington, 98121, 1-800-426-0347, Telex 328840. Distributed worldwide.

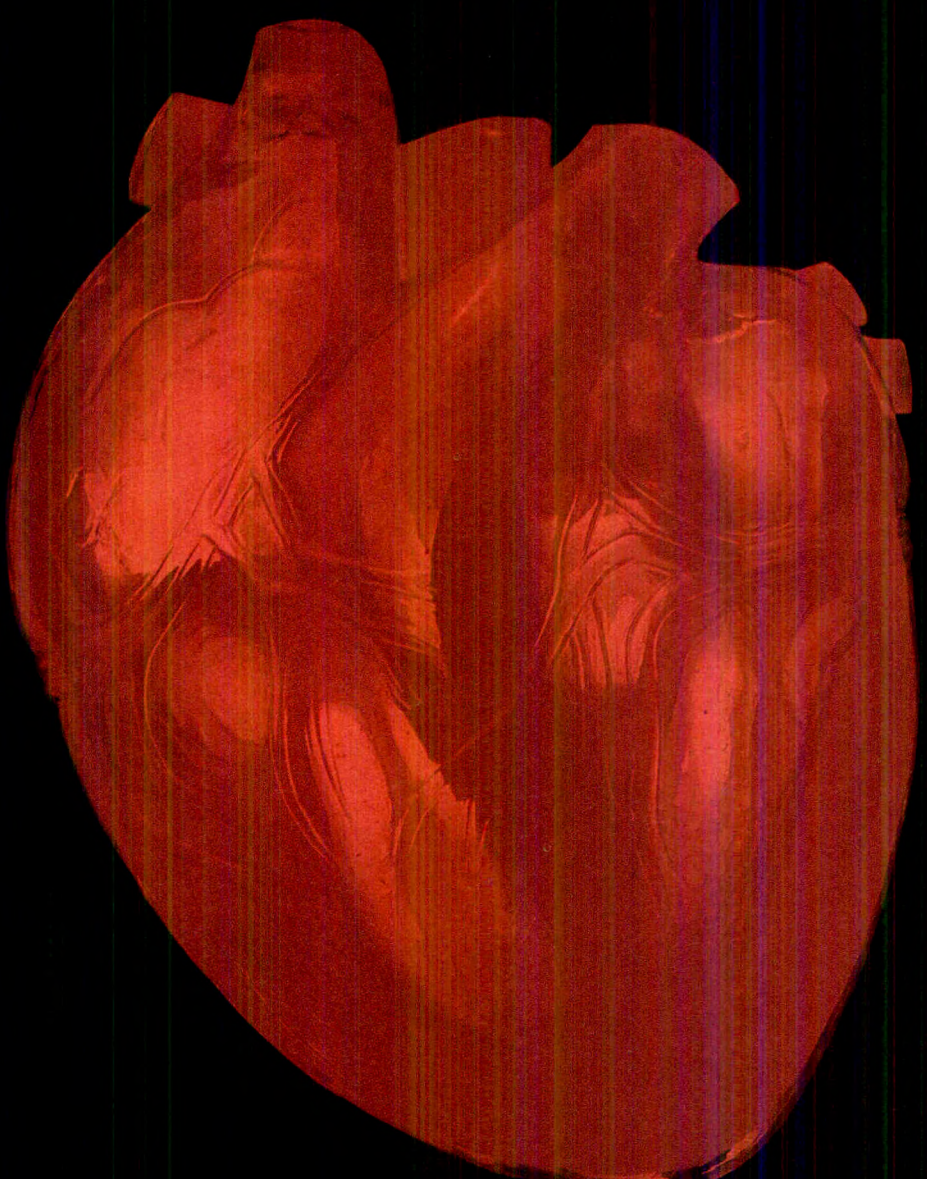
Our new Versatrax pacemakers keep
a heart beating like a heart.



Introducing Versatrax™ physiological cemakers-the truly universal pacing system.

x™ pacemakers are physio-nits that sense and pace in mbers, precisely respond-our patient's intrinsic car-ythms. The resultant d hemodynamics of syn-is dual chamber pacing s the quality of life in a ectrum of your patients. **trax™ pacemakers can be dapted to each of your particular needs because amming capability.** Use of the CENSYS™ programmer provides 3 pacing modes: DDD, DVI, or VVI. Fine tune Versatrax™ physiologic pacemakers to each patient's specific symptomology through program options which include: lower rate, upper rate, pulse width, A-V interval, sensitivities, and more.

Versatrax™ physiologic pacemakers are the longest lived multimodal pacing systems available today. You and your patients can anticipate an 8 year battery life expectancy.

Medtronic's commitment to you doesn't end with the world's quality and reliability standard in pacing products. For consultation any time, special assistance, patient follow-up services, or more information, call (toll free) **1-800-328-2518,** or mail our coupon. It's all just part of the Medtronic difference.

Versatrax™ Model 7000 Universal A-V Pacemaker

Intended Uses

The Model 7000 universal A-V pulse generator has a wide range of applications in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation. With the Model 7000 programmed in the A-V universal (DDD) mode, such indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias.
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000 may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias.
- Atrial and ventricular ectopic arrhythmias.

At any time the Model 7000 can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry.

Contraindications

General. There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode. The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms of slow retrograde conduction.

DVI Mode. In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy. Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site. Electrosurgical units should never be used in the presence of unipolar pulse generators because of the danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

Defibrillation. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCK2

DEFINITION OF VENTRICULAR TACHYCARDIA

The careful and meticulously analyzed study by Bigger et al.,[1] while undoubtedly of value in further characterization of postinfarction ventricular tachycardia (VT), starts with an unfortunate choice of definitions and channels its discussion to the hardly novel "clinical implication" that "VT may be the harbinger of subsequent arrhythmic death."

To define VT as the authors did—as 3 consecutive complexes of ventricular origin regardless of their rate—would include ventricular escape rhythms, including those produced by electrical pacemakers. The authors' definition is at variance with the standard electrocardiographic nomenclature over the past several decades.[2–4] The only "justification" for this appears to be a similar mortality observed for rates above and below 100 beats/min. This may be spurious, since there is no way of knowing how the patients actually died with respect to the authors' subdivision.

The implication about subsequent arrhythmic death is similarly unwarranted, given that the *observed* 1,370 episodes of VT behaved rather innocuously at the time of the recording. Their predictive value is further weakened by the reported lack of quantitative relation between the frequency of VT and subsequent death in individual patients. Furthermore, the rarity of the R-on-T phenomenon in this series and its frequency in the cases of sudden death observed outside hospital[5,6] tend to imply different arrhythmic mechanisms at the time of actual sudden death.

The strong predictive indexes of sudden death, namely the left ventricular contraction abnormalities and the anatomy of the coronary artery disease,[7,8] are substituted by the somewhat imprecise category of clinical left ventricular failure, presumably present in 29% of the authors' patients, for comparison with the predictive value of VT. The case for the independent predictive value of VT in this setting has yet to be made.

REPLY: We appreciate Dr. Nikolic's interest in ventricular arrhythmias occurring in the late hospital phase of acute myocardial infarction. His comments indicate dissatisfaction with our current knowledge in this area and a desire to have answers to many unresolved questions. We share his interest in these matters. Dr. Nikolic posed questions about 3 issues raised in our report on ventricular tachycardia (VT): (1) our definition of VT, (2) the hypothesis that the presence of VT in a predischarge Holter recording may indicate future *arrhythmic* death, and (3) the relation between VT and other functional risk predictors, especially left ventricular dysfunction. All of these are controversial and worthy of discussion.

Definition of VT: VT has been variously defined in terms of the number of consecutive ventricular premature depolarizations and the rate. Although the modal electrocardiographic definition for VT is three or more consecutive ventricular premature depolarizations, definitions requiring 4 or 5 consecutive ventricular complexes are still used by some workers. Clinical electrophysiologists often use 5 or 10 consecutive ventricular premature depolarizations in response to progammed ventricular stimulation as a definition of nonsustained VT. Also, the rate requirement in the definition of VT varies; the 3 most common in order of frequency of use are 100 beats/min, 120 beats/min, and any rate.[1,2] Our decision a priori to include all *spontaneous* episodes of 3 or more consecutive ventricular premature depolarizations in our study was made because of the total ignorance about the prevalence, characteristics, and significance of VT in the late hospital phase of myocardial infarction when we began our study. We anticipated that we might find some justification for a rate component in the definition of VT by examining the relation between the average VT rate and subsequent clinical events (see Figure 1B in our report). In this analysis, 2 interesting facts emerged. First, the interectopic interval in an episode of VT often is extremely variable. Second, there is not yet *any hint* of a relation between the rate of an episode of consecutive ventricular premature depolarizations and mortality. A study by Kleiger et al.[3] took an approach similar to ours. To avoid the semantic problem of using the term *tachycardia* for episodes with rates less than 100 beats/min, they chose the term *ventricular runs*. This addresses the issue in an intelligent way, permitting continuing studies of ventricular arrhythmias without aggravating traditional definitions. Very large studies will be needed to resolve the questions about the significance of various characteristics of ventricular runs. We would encourage investigators to keep data on a full range of rates to enhance our knowledge in an area where there is a great void.

Implications about mechanisms of death: This is another difficult and controversial topic. Epidemiologists are frustrated in their attempts to classify deaths in a functional, that is, mechanistic sense. At present, the fact that death has occurred, the time between symptoms and death, and the cardiac or noncardiac nature of death are the mainstays of classification. Attempts to attribute death to ischemia, left ventricular power failure, or arrhythmias are fraught with difficulty because of data available at the time of death and because of complex interrelations among these functional entities. In our section on clinical implications, we discussed the *hypothesis* that VT may predict *arrhythmic death* but emphasized that the complex interactions among functional risk factors make alternative hypotheses tenable. Also, we discussed how to gather information about the interactions and how to use it in managing patients at present. We also are frustrated by the limitations in classifying postinfarction deaths and encourage efforts to advance the state of the art.[4,5]

Relation between VT and other risk factors: This is one of the most difficult issues raised by Dr. Nikolic since the studies to date, including our own, are so small. Dissection of the relations among VT, ischemia, left ventricular dysfunction, and death requires a large effort and has not yet been achieved.[1,6–8] First, a study with a large number of patients with VT and a large number of deaths is needed; about 100 of each would be desirable. The sample should be unbiased, that is, representative. Second, acceptable measures for ischemia, left ventricular dysfunction, and VT are needed. Finally, an accurate assessment of death in functional terms is needed. Our current hypothesis about what might be found in such a study is that VT would be significantly and importantly related to left ventricular dysfunction and significantly less so to ischemia. In addition, adjusting for these interactions, VT would have a significant and important association with cardiac death in the year after myocardial infarction. We are not at all certain that VT would be more strongly associated with "arrhythmic death" than other modes of death, if, indeed, the functional mode of death can be identified with sufficient precision.

CARDIOLOCUTION AND DYSRHYTHMIA

The epithet *cardiolocution* which appears in the title of Spodick's editorial[1] neatly exemplifies the very problem he discusses. *Cardiolocution* is truly a neologism,* a coined word, in this instance one of known provenance. It is a nonce word, created for the occasion—cute perhaps, but unnecessary and ephemeral. It is a neat irony that this term precedes an editorial in which the author uses his scientific knowledge, extensive vocabulary, and concern for language† as a kind of multiheaded missile to attack the linguistically accurate *dysrhythmia* and to defend the indefensible *arrhythmia*.

Dysrhythmia has more than the virtue of ringing right, as Spodick agrees, cheerfully damning with faint praise. Etymologically, it accurately describes the medical condition that the cardiac rhythm is disturbed. The generally accepted but inaccurate *arrhythmia* does not conform with classic Greek usage, as an article in the *British Heart Journal*[2] claimed some years ago. To the word-sensitive physician or patient, it suggests, erroneously and humorously, if one has a taste for such humor, that rhythm has ceased. *Dorland's*, of course, in its Analytical Word List, defines the prefix *a* as a "negative prefix" and *dys* as a prefix meaning "bad or improper." I need not list sample medical terms in which these prefixes are correctly used.

I have written to medical editors, publishers, authors, and pharmaceutical houses to urge the use of "dysrhythmia," in the interest not merely of linguistic purity but also of medical accuracy. My correspondence is available for your perusal. As a result, Parke-Davis has changed its advertising, and now uses the term *dysrhythmia*. Searle will do so, and others are contemplating changing.

Philip R. Trommer, MD, Philadelphia, Pennsylvania

1. **Spodick DH.** Cardiolocution. The cardiologist's assault on English. Am J Cardiol 1981;48:973–974.
2. **Krikler D.** What to call arrhythmias? Br Heart J 1978;40:1325–1326.

REPLY: Two cheers for Dr. Trommer. *Cardiolocution* is indeed a nonce word, created for the occasion. I did not use it in the text and I will not use it again—nor do I expect it to enter our vocabulary. Other writers have used terms such as *Medispeak*, and in my editorial I referred to George Orwell, who created the words *newspeak* and *doublethink*. Orwell is highly regarded for these creations and they, like *cardiolocution*, were never intended for general use.

Trommer has exercised himself mightily over the issue of *arrhythmia* versus *dysrhythmia*. This was a microscopic part of my message and I attributed it to the distinguished editor of the *British Heart Journal* (who is the genuine Greek scholar), as Trommer recognized. Trommer caught the words but missed the spirit of that part of my essay, summarized in its last sentence: "All these examples of medical jargon are linguistically unattractive but not really harmful because their meaning remains intact and no physician will be misled by them." Indeed, this was only an introduction to the subsequent material which embodied my real aims. Finally, the fact that Trommer cites advertisers who employ—or, perhaps more accurately, *deploy*—certain language is hardly an endorsement of its accuracy.

Trommer's definition of *neologism*, cited from *Dorland's*, is too clever by half. That is only one—and not the principal—definition of *neologism*, as Trommer ought to know. We all have enough Greek to know that it literally means "new word," and *Stedman's Medical Dictionary* gives "a new word or phrase, or an old word used in a new sense," as its *first* definition. Furthermore, since even for medical communication the best English should be intelligible to the layman, *Webster's Third New International Dictionary*, on page 1516, gives its *first* definition of *neologism* as "a new word, usage or expression."

On second thought, only one cheer for Dr. Trommer.

David H. Spodick, MD, DSc, Worcester, Massachusetts

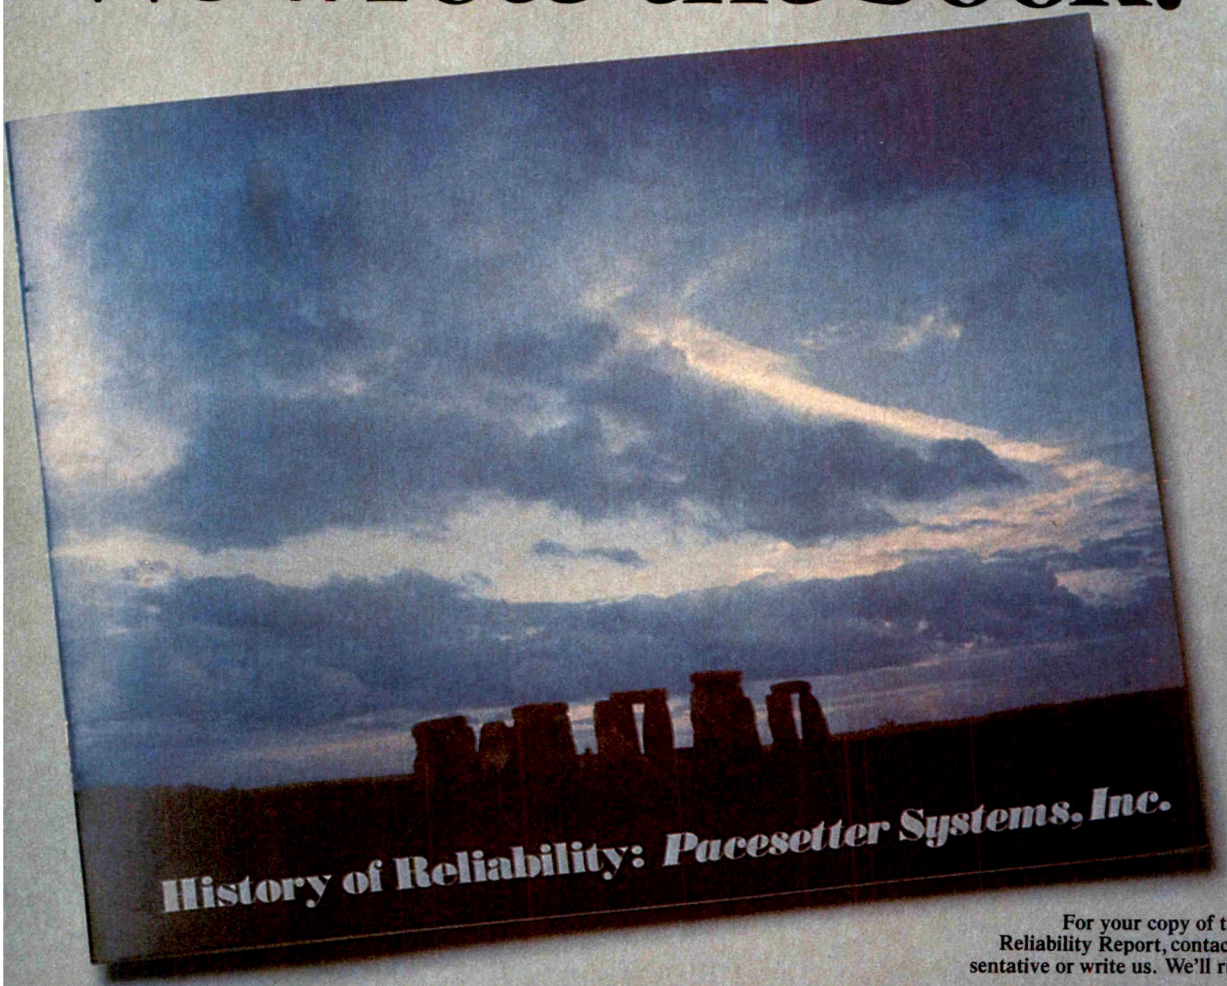
---

* *Neologism* is defined as "a meaningless word uttered by a psychotic or delirious person" by *Dorland's Illustrated Medical Dictionary*.

† An erudite and scholarly article on the subject is entitled "Medical Language, An Exclusive Code," by Nicholas P. Christy, published in Transactions & Studies of the College of Physicians of Philadelphia, Series 5, Vol 3, No. 4, Dec. 1981:301–311. He also fully discusses Orwell.

Another reason we're called PACE*SETTER:*

Reliability? We wrote the book!



For your copy of the Pacesetter Reliability Report, contact your representative or write us. We'll rush it to you.

Now there's documented evidence of Pacesetter's outstanding record of pacemaker reliability. A new report, just published, which details the performance of some 20,000 implants based on actual clinical experience, is available now, for the asking.

Pacesetter's innovative Programalith® series of demand pulse generators achieved an impressive reliability score of *99.58%* over three years—pointing out that Pacesetter reliability is significantly higher than industry standards.

It also points out something else: you can have complete confidence when you prescribe Programalith.

Because when we make a pacemaker, we do it by the book.

ANGINA
INDERAL® (PROPRANOLOL HCl) TODAY CAN TAKE THE CONCERN OUT OF TOMORROW.
Fewer angina attacks, less anginal pain, greater freedom from fear. That's what early use of INDERAL (propranolol HCl) can mean to today's angina patients. INDERAL works to reduce myocardial oxygen demand—by lowering the heart rate... reducing systolic blood pressure... decreasing contractility. Because it helps balance myocardial hemodynamics, INDERAL enables selected patients to do more—with less need for nitroglycerin, less fear of pain. When conventional measures are inadequate, prescribe INDERAL for angina early. INDERAL does more—so your patients may do more.
INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.
Please see following page for Brief Summary of Prescribing Information.

INDERAL®
(PROPRANOLOL HCl)

THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE. In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA. Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY. Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System*: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal*: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic*: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory*: bronchospasm. *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous*: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings*: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

Millar Catheter-Tip Pressure Transducers are now more stable and durable than ever before !

Our new MT-10™ Pressure Sensor makes it all possible

The totally new MIKRO-TIP® MT-10™ pressure sensor, manufactured with the latest semiconductor technology, is extremely durable, with several times the impact resistance of previous sensors. It is insensitive to ambient light and to changes in temperature and provides accurate, high fidelity pressure measurements with exceptional baseline stability.

In addition, transducers with the new MT-10™ pressure sensor have all the excellent features of our previous transducers, such as good linearity, negligible hysteresis, large output signal with good signal-to-noise ratio, and high frequency response for the detection of intracavitary sounds.

The new MT-10™ pressure sensor has been used selectively in transducers for many months and is now the standard pressure sensor in all MIKRO-TIP® Catheter Pressure Transducers, size 5F (1.7mm o.d.) and larger. These transducers are compatible with existing Millar accessories.

Millar offers a wide variety of catheter pressure transducers for applications in Cardiology, Urology and Gastroenterology. Models are available with one or more pressure sensors optionally with lumen(s) for simultaneous fluid sampling or high speed injection. Also available are models with a fluid-velocity sensor and one or more pressure sensors. Catheter sizes range from 3F (1mm o.d.) through 9F (3mm o.d.). You select the size and configuration that's right for your specific need.

For complete information contact Millar, the world's largest manufacturer of high fidelity catheter-tip pressure transducers for clinical and research applications.

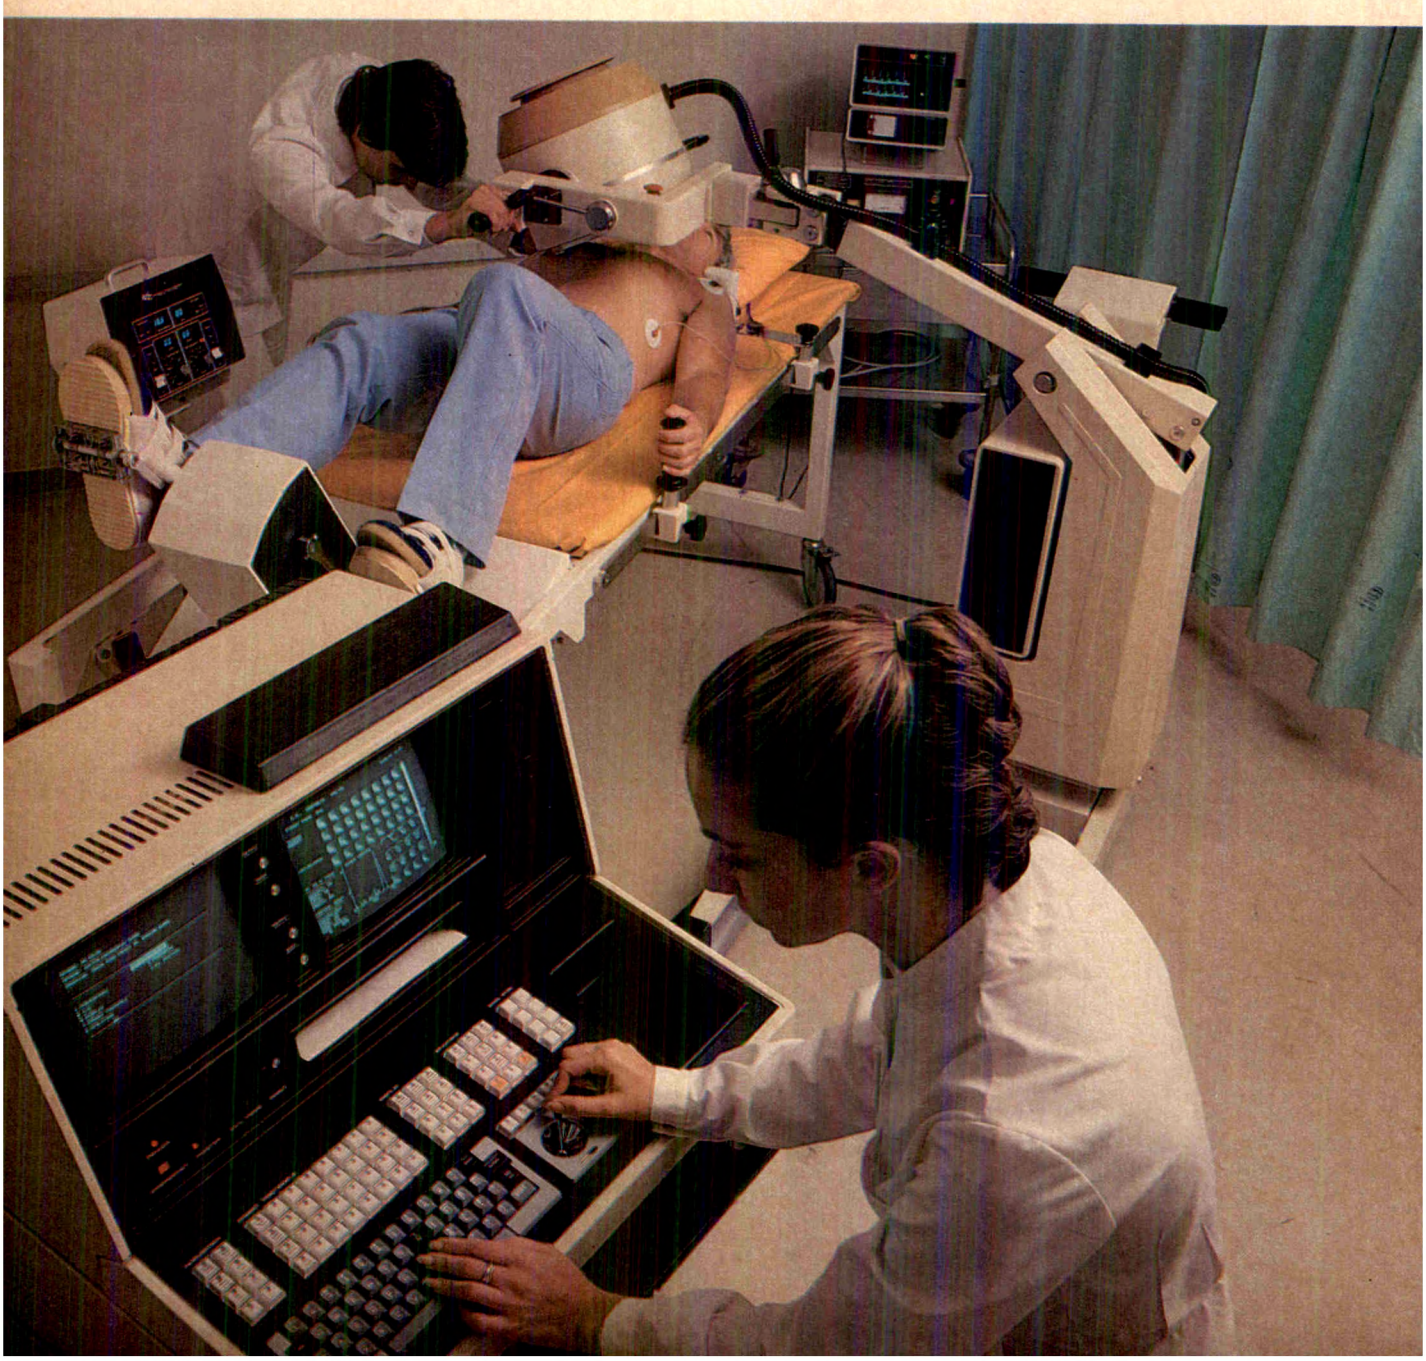
radionuclide cardiography comes of age

Apex 215M

The Cardiologist's Own Nuclear Camera

Visit our Booth at the Meeting of the American Heart Association (AH in Dallas. November 15-18, 1982.



Nuclear Cardiology: it grows more authoritative every day. Apex 215M is fast becoming the first choice in cardiac nuclear imaging. And with good reason.

Universal Cardiological Capability

Apex 215M is a compact digital nuclear camera — fully mobile and exceptionally maneuverable.

Apex 215M's image quality is far superior to that of any other camera. Clinical count rates in first-pass studies exceed 200K CPS. Resolutions of 1.8 mm bars are particularly valuable in Tc and Tl scintigraphic studies of myocardial infarction and ischemia. And superfast data handling enables rest/exercise equilibrium studies at 64 frames per cycle.

Dedicated Cardiological Software

Today's knowledgeable physician appreciates Apex 215M's broad spectrum of dedicated software:

- Global and Regional Ejection Fraction
- End Diastole/Systole Volumes
- Paradox Imaging
- Fourier, Phase and Amplitude Imaging

and many more. And an entire new series of Apex cardiological programs is currently being tested.

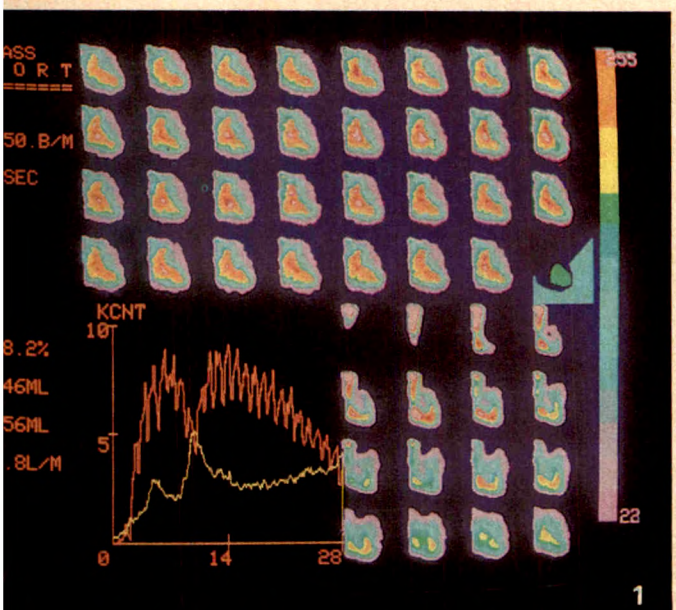
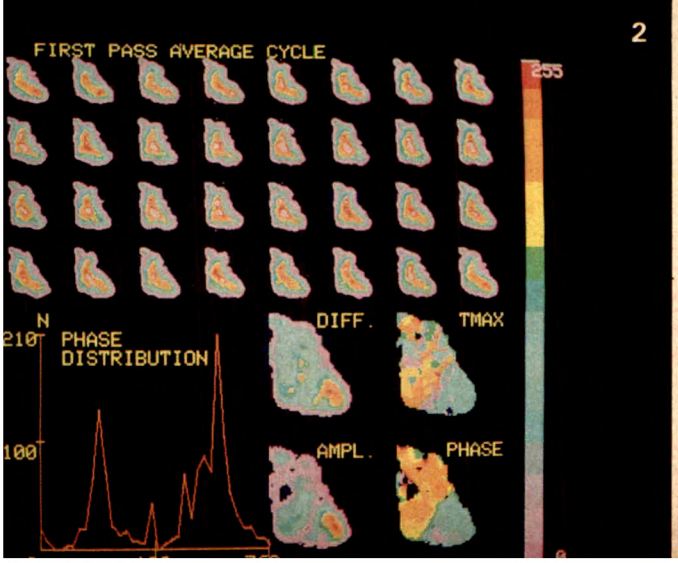
Call Toll Free: 800-343-9504.

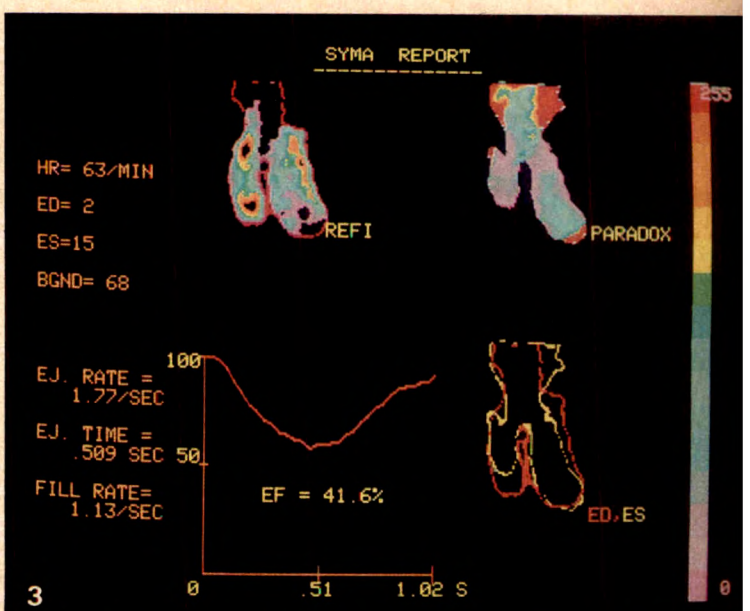


1

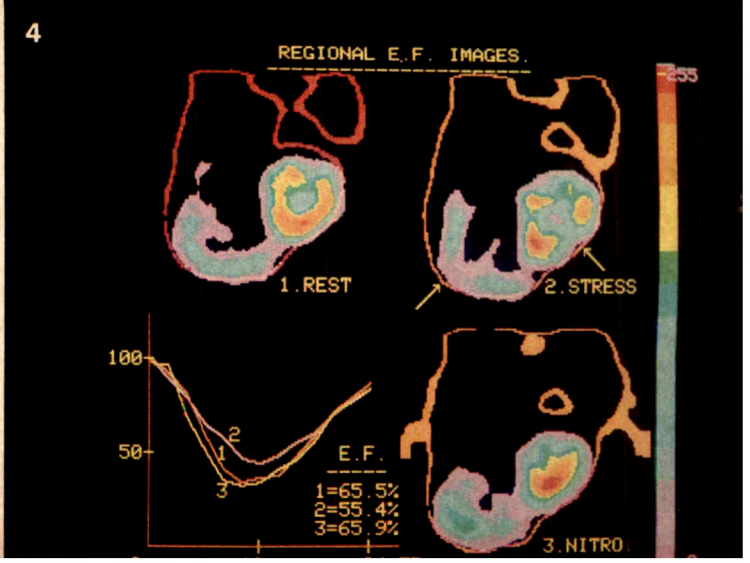


2

Photos 1 & 2: Apex 215M's high count rates enable superior definitive first-pass studies. Typical of its capabilities are global and regional ventricular function analysis and direct quantification through volume.



3

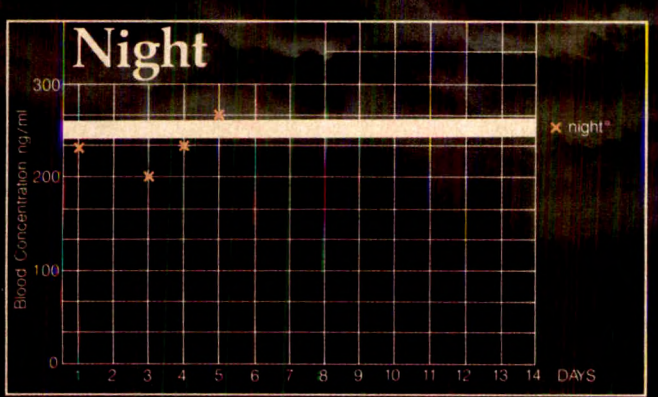


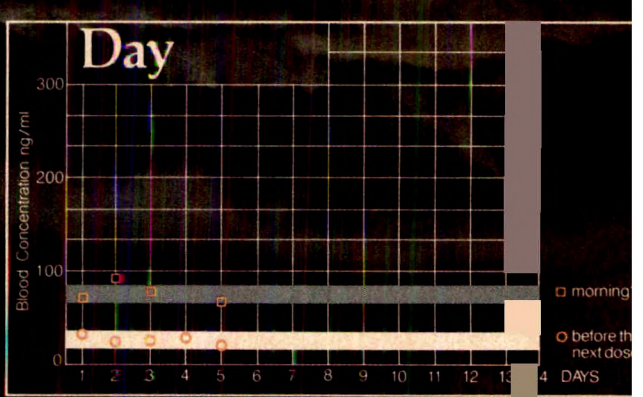
4

Photos 3 & 4: Apex 215M can clearly display various global and regional functions on a single image monitor. In these examples, ventricular functions in a resting heart appear above; the lower image compares the resting heart with two different intervention situations.

The difference between night...

RESTORIL® (temazepam) blood levels after consecutive nightly 30-mg doses[1,2]





RESTORIL® (temazepam): Effective at night—little residual daytime medication—patients awake alert and refreshed

The half-life of RESTORIL (temazepam) parallels normal sleep time. In contrast, the major active metabolite of flurazepam has a 65-hour mean half-life. With RESTORIL therapy, a major portion of active material is cleared by early morning—enabling patients to awake alert and refreshed.

No significant impairment of daytime activities

In double-blind, placebo-controlled studies,[3,4] no detectable impairment in cognitive function or motor coordination occurred in patients who had taken a 30-mg dose of RESTORIL (temazepam) the night before. In the same studies, poorer performance scores were attained by patients who had taken a 30-mg dose of flurazepam prior to bedtime.

Patients receiving benzodiazepines should be cautioned about possible combined effects with alcohol and other CNS depressan and about operating machinery or driving a vehicle after ingesting the drug.

Sleep time and quality significantly improved

In 21 double-blind studies[5] involving 1,221 adult patients (508 of whom received RESTORIL capsules), RESTORIL therapy prove highly effective from the first night of administration. RESTORIL (temazepam) is indicated for the relief of insomnia associated wit the complaints of difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakenings from the first nigh REM sleep remained essentially unchanged. Patients reported a significant improvement in the general quality of sleep.

*night: 3 hours after a nightly 30-mg dose. †morning: 12 hours after a nightly 30-mg dose. ‡before the next dose: 24 hours after a nightly 30-mg dose

RESTORIL® C IV

15 mg
30 mg
capsules

(temazepam)

lypnotic action with insignificant accumulation

RESTORIL® (temazepam) C-IV capsules
One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment, should be considered.

CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

Laboratory Tests: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

Pregnancy: Pregnancy Category X. See Contraindications.

Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.

ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). SDZ1-159

Before prescribing, see package insert for full product information.

Mary Allen Engle, M.D.
Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Gallen, M.D. JAMA, November, 1981

yes... because it's Sanka®

BRAND
DECAFFEINATED COFFEE

Antihypertensive therapy often involves diet modification–restricting favorite foods and beverages. But there's one enjoyable beverage hypertensive patients can continue to enjoy: coffee.

Sanka® is 100% real coffee, but it's 97% caffeine-free. That's why it will not exacerbate underlying hypertension in patients who are bothered by too much caffeine.

And because Sanka® tastes good, it aids patient compliance. What's more, it's available in instant, freeze-dried and ground forms. It can even be found at restaurants in convenient single-service packages.

Nonstimulating Sanka® is ideally suited to many special diets. And physicians recommend it more than all other brands of decaffeinated coffee combined.

TAMI

Together Instromedix and Cardiac Datacorp bring you the best in 24-hour arrhythmia monitoring.

No matter when a patient suffers symptomatic arrhythmias, there's little a physician can do without timely, accurate documentation of the episode.

Now Instromedix, the most-experienced manufacturer of widely-used arrhythmia monitoring systems, teams up with Cardiac Datacorp, the most experienced cardiac monitoring service, to bring you state-of-the-art transtelephonic cardiac monitoring equipment and service.

Instromedix Arrhythmia Monitoring Systems ensure accurate, 24-hour AHA quality electrocardiograms that can be stored in a computer-type memory until transmitted and received telephonically for documentation and analysis.

Cardiac Datacorp's expertise in monitoring trans-telephonic ECG's makes sure you get accurate interpretation of symptomatic episodes. Trained technical personnel, directed by board-certified cardiologists, provide the analysis 24-hours a day, seven days a week.

Whether you decide to operate your own Instromedix Arrhythmia Monitoring System or to use the transtelephonic services of Cardiac Datacorp, you can rest assured you'll be providing the best in 24-hour monitoring for your patients.

For more information about purchasing, leasing, or renting Instromedix equipment in the United States, contact Cardiac Datacorp at the phone number below.

Outside the U.S., please contact Instromedix directly.

Visit us at booths E37/E39 and E38/E40 at the AHA show in Dallas, November 15-18.

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decrease excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxi (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: Th drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/o disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTES TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricula tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMA TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulo cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, an syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, nigh blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intens pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribin

The American Journal of CARDIOLOGY®

25th anniversary

The first issue of THE AMERICAN JOURNAL OF CARDIOLOGY appeared in January 1958, and therefore this issue marks the end of 25 years of publication. We look forward to further progress within these pages during the next 25 years.

A YORKE MEDICAL JOURNAL

Contents on Pages A9 and A10

When more than a thiazide is needed...

ALDOMET® TABLETS 500 mg, 250 mg, and 125 mg

(METHYLDOPA | MSD

an agent well matched to the profile

With increasing age...
incidence of certain concurrent disorders increases

ALDOMET may be used in a wide range of older hypertensives, including those with:

- **ventricular hypertrophy/cardiac failure***
- **peripheral vascular disease**
- **diabetes mellitus**
- **hyperuricemia/gouty arthritis**

judicious exercise may be desirable

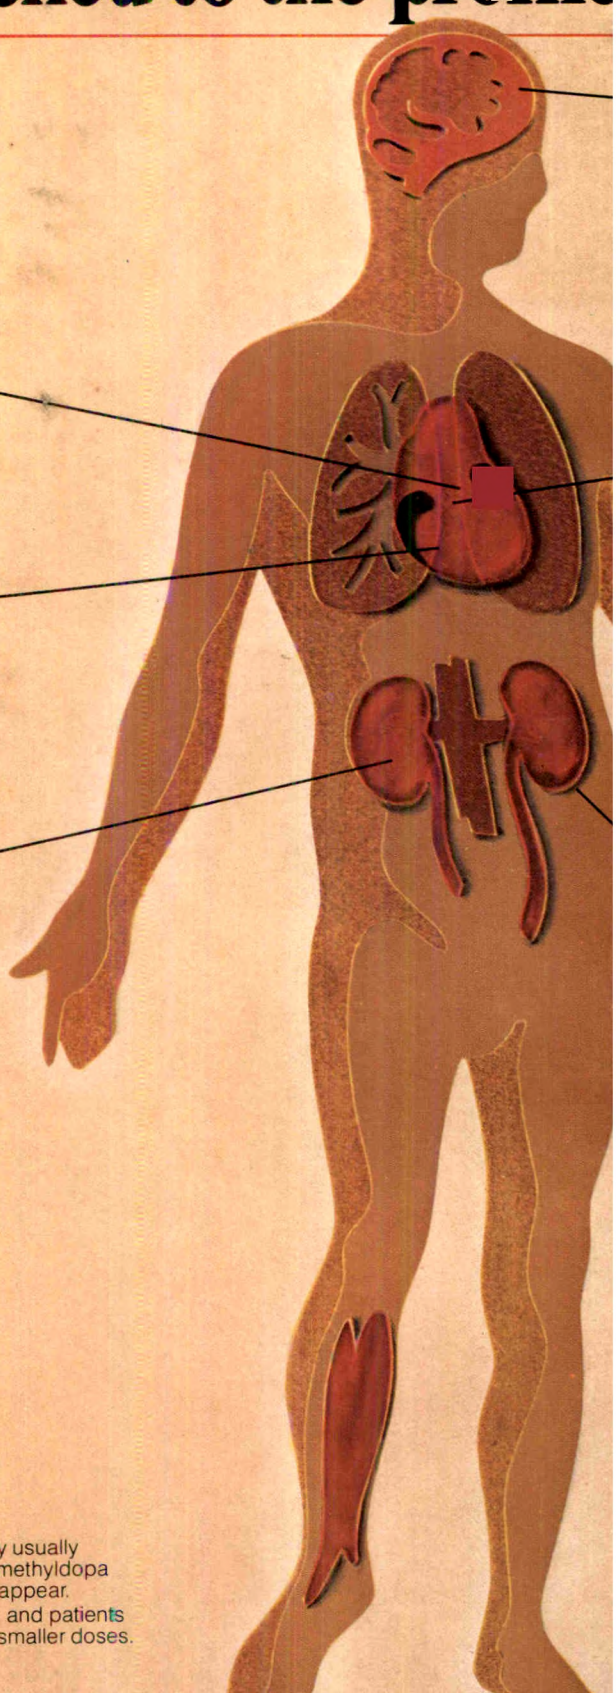
ALDOMET usually does not interfere with the cardiovascular response to exercise.

renal function often diminished

ALDOMET usually does not reduce glomerular filtration rate, renal blood flow, or filtration fraction.†

compliance often a problem

ALDOMET provides b.i.d. dosage convenience for many patients.



*Edema (and weight gain) may occur and may usually be relieved by use of a diuretic. Discontinue methyldopa if edema progresses or signs of heart failure appear.

†Methyldopa is largely excreted by the kidney, and patients with impaired renal function may respond to smaller doses.

# of a wide range of older hypertensives

ability to autoregulate cerebral blood flow with postural changes often decreased

With ALDOMET® (Methyldopa, MSD), symptomatic postural hypotension is infrequent. Syncope in older patients may be avoided by lower doses.

cardiac output and heart rate usually normal

ALDOMET has no direct effect on cardiac function, and cardiac output usually is maintained.

total peripheral resistance usually high

ALDOMET lowers blood pressure, apparently by lowering total peripheral resistance.

ongoing therapy usually required

ALDOMET has demonstrated a high degree of efficacy in long-term therapy.

plasma renin activity usually low but may be normal or high

With ALDOMET, normal or elevated plasma renin activity may decrease.

ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, or if previous methyldopa therapy has been associated with liver disorders.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed.

Syncope in older patients may be related to an increased sensitivity and advanced arteriosclerotic vascular disease. This may be avoided by lower doses.

MSD
MERCK

ALDOMET® (Methyldopa/MSD)

Tablets, containing 125, 250, or 500 mg methyldopa; Oral Suspension, containing 250 mg methyldopa per 5 ml and alcohol 1%.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions. With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood. At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients. Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, prolonged carotid sinus hypersensitivity, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, colitis, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Bone marrow depression, leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Dermatologic:* Rash as in eczema or lichenoid eruption; toxic epidermal necrolysis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, hyperprolactinemia, amenorrhea, impotence, decreased libido, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

FROM THE EDITOR

Speeding Up the Manuscript-Reviewing P

All reviewers for the *AJC* are asked to send their reviews to the Editor within 3 weeks. When this time period is met by each reviewer, authors can be notified that their manuscript is accepted or rejected within a month. Although this time sequence operates well for most manuscripts submitted to the *AJC*, some reviewers fail to return their reviews to the Editor for several additional weeks. Indeed, I have been surprised by the length of time some reviewers retain a manuscript before returning it, with or without their opinion, to the Editor.

The "frequent" author is usually a "frequent" reviewer, but the 2 hats are worn at different times. When authors submit manuscripts to a journal, their patience for delay in receiving the "acceptance" or "rejection" decision is generally short; however, when these same authors become reviewers, their patience for delay appears much longer. Reviewers should treat authors as they would like to be treated when they are authors—*this might be the golden rule of reviewing.*

How can a reviewer decrease the length of time between receipt of a manuscript and its return to the Editor? One procedure which has proved useful to me is to *examine the manuscript brief*
the subject of the manuscr
several days before the revi
manuscript concerns a sub

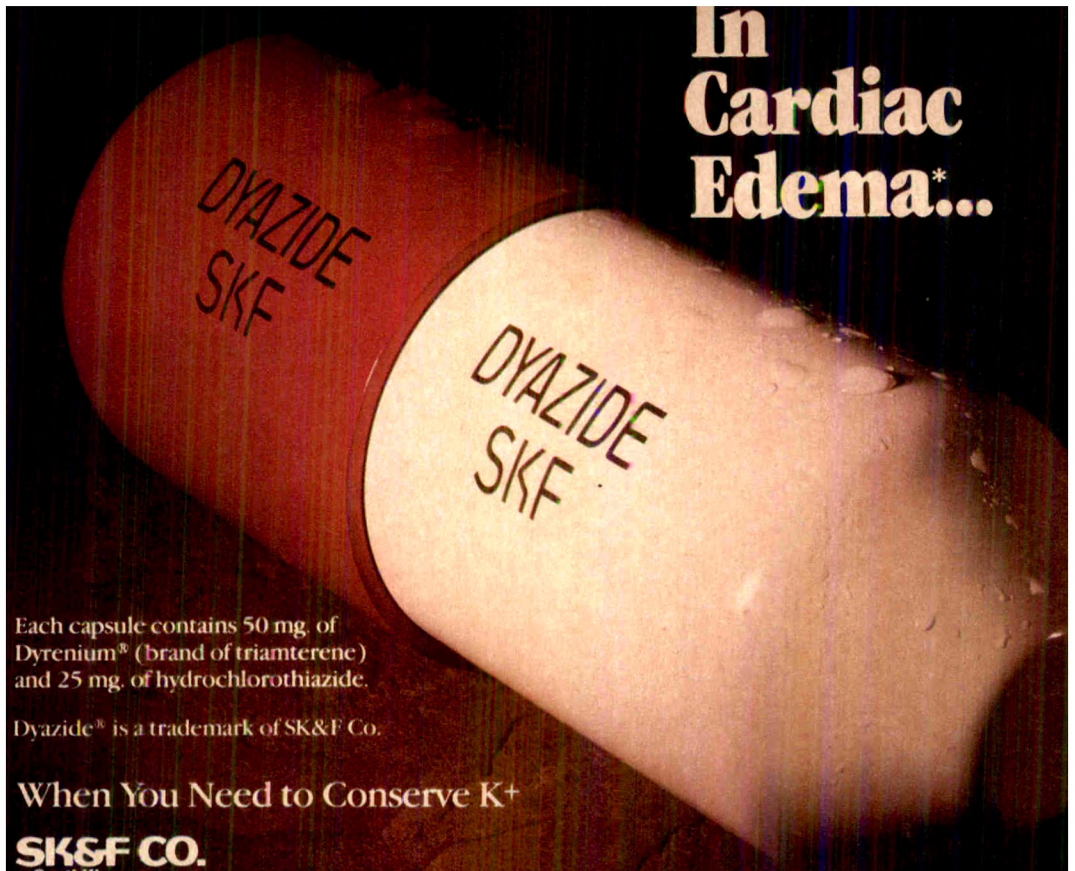
UNIVERSITY OF WASHINGTON LIBRARY

In Cardiac Edema*...



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

When You Need to Conserve K+

SK&F CO.
a SmithKline company
Carolina, P.R. 00630

Serum K+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

★ **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been recorded. Thiazides have been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both; hyperglycemia and glycosuria (diabetic insulin requirements may be altered); hyperuricemia and gout; digitalis intoxication (in hypokalemia); decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

THE AMERICAN JOURNAL OF CARDIOLOGY® (ISSN 0002-9149) December 1982, Vol. 50, no. 6 (USPS: 505–750).

Member, American Business Press, Inc. and Audit Bureau of Circulations. Published monthly except January, March, and May, semimonthly, by Technical Publishing, a Division of Dun-Donnelley Publishing Corporation, a Company of The Dun & Bradstreet Corporation. James B. Tafel, Chairman, John K. Abely, President. Executive, Editorial and Advertising Offices: 875 Third Ave., New York, NY 10022. Printed in Easton, PA.

SUBSCRIPTIONS: Solicited only from cardiologists and other physicians. Publisher reserves the right to refuse unqualified subscribers. Subscribers agree that no article or any part thereof published in any editions of the American Journal of Cardiology received under this subscription agreement may be copied, recorded or reproduced in any form or by any means, electronic or mechanical, including, among other things, photocopying or the storing of part or all of such articles on any information retrieval system, without the written permission of the Publisher. Address correspondence regarding subscriptions and changes of address to: THE AMERICAN JOURNAL OF CARDIOLOGY, 875 Third Ave., New York, NY 10022. Please include your zip code and, in case of change of address, copy of old address label. Changes of address must reach the Journal one month preceding month of issue. Single copy price: Regular issues $10.00; Symposium and special issues $12.00. Subscription rate for individuals in field of publication: United States 1 year $48, 2 years $87; Canada 1 year $55, 2 years $101; Foreign 1 year $62 ($162 air mail), 2 years $108. Residents, Interns, Medical Students: United States $26 for 1 year. The Journal is not responsible for replacing missing issues unless the Circulation Department is notified of nonreceipt within 3 months of issue date.

Second class postage paid at New York, New York 10001 and at additional mailing office. Printed in U. S. A. Trademark® in U. S. Patent Office.

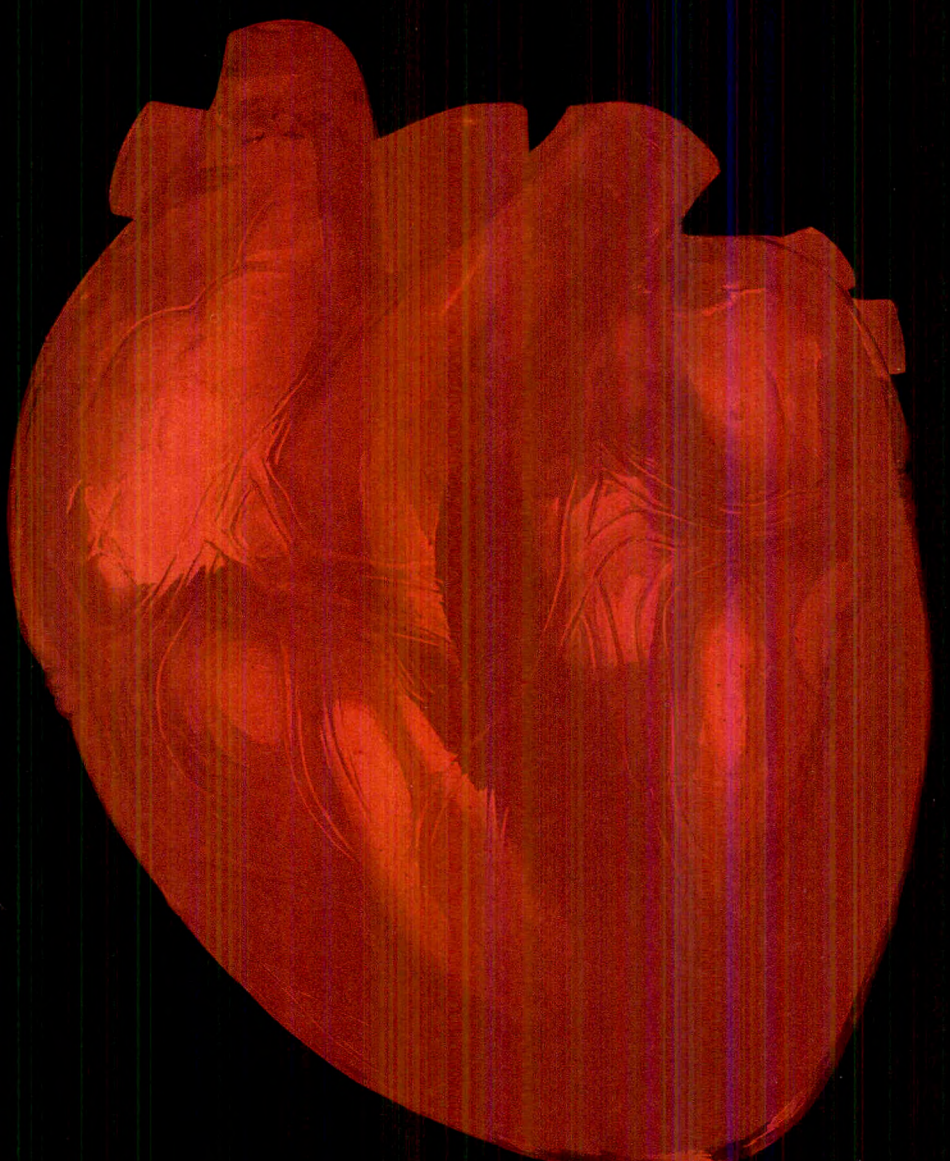
Our new Versatrax pacemakers keep a heart beating like a heart.



Introducing Versatrax™ physiological pacemakers-the truly universal pacing system.

ersatrax™ pacemakers are physio-gical units that sense and pace in oth chambers, precisely respond-g to your patient's intrinsic car-iac rhythms. The resultant nproved hemodynamics of syn-hronous dual chamber pacing nproves the quality of life in a oad spectrum of your patients.

Versatrax™ pacemakers can be asily adapted to each of your tient's particular needs because programming capability. Use of the CENSYS™ programmer provides 3 pacing modes: DDD, DVI, or VVI. Fine tune Versatrax™ physiologic pacemakers to each patient's specific symptomology through program options which include: lower rate, upper rate, pulse width, A-V interval, sensitivities, and more.

Versatrax™ physiologic pacemakers are the longest lived multimodal pacing systems available today. You and your patients can anticipate an 8 year battery life expectancy.

Medtronic's commitment to you doesn't end with the world's quality and reliability standard in pacing products. For consultation any time, special assistance, patient follow-up services, or more information, call (toll free) **1-800-328-2518,** or mail our coupon. It's all just part of the Medtronic difference.

Versatrax™ Model 7000 Universal A-V Pacemaker

Intended Uses

The Model 7000 universal A-V pulse generator has a wide range of applications in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation. With the Model 7000 programmed in the A-V universal (DDD) mode, such indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias.
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000 may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias.
- Atrial and ventricular ectopic arrhythmias.

At any time the Model 7000 can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry.

Contraindications

General. There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode. The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms of slow retrograde conduction.

DVI Mode. In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy. Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site. Electrosurgical units should never be used in the presence of unipolar pulse generators because of the danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

Defibrillation. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.
